EBV-ASSOCIATED LEIOMYOMAS FOLLOWING HAPLOIDENTICAL TRANSPLANTATION FOR X-LINKED SEVERE COMBINED IMMUNODEFICIENCY DISEASE

Robertson, K.A.[1], Alturi, S.[1], Neville, K.1, Davis, M.[1], Marshalleck, F.E.[1], Buckley, R.H.[2], Nelson, R.P.[1] [1]Indiana University School of Medicine, Indianapolis, IN; [2]Duke University Medical Center, Durham, NC.

In the setting of transplantation, Epstein-Barr virus (EBV) is most commmonly associated with posttransplantation lymphoproliferative disease; however, there are reports of EBV associated leiomyomas for which the virus has some tropism. We wish to report the first case of EBV-associated leimyomas following haploidentical BMT for X-linked severe combined immune deficiency (SCID). Twin A is an 8-year-old boy who along with his syngeneic twin (B) received a paternal T-cell–depleted haploidentical BMT for X-linked SCID at 10 days of life. Twin B experienced rapid donor T-cell engraftment with restored cellular function. Twin A's course was complicated by incomplete donor T-cell engraftment, multiple infections, and GVHD. Twin A received a booster twin-to-twin infusion of unfractionated marrow, resulting in an improved lymphocyte counts, mitogen stimulation response, and clinical improvement without worsening of GVHD. The patient (twin A) did well over the next 6 years until he developed fatigue, weight loss, and exercise-induced shortness of breath. CT scans revealed bilateral renal masses (4 on the right and 2 on the left) with a left pleural-based lung mass. Percutaneous renal biopsy demonstrated leiomyoma with a spindle cell histology. The tumor cells were positive for Ki-67 and actin, but negative for S-100 protein and HMB45. EBV PCR on paraffin-embedded tissue was positive. EBV serologies were unhelpful on both twins as they remain on intravenous immunoglobulin supplementation, but EBV PCR was negative from the peripheral blood of twin B and positive for twin A at 2400 copies per mL. T-cell chimerism studies showed a decrease in donor T-cell engraftment in twin A. Twin A continued to show weight loss with persistant symptoms and was subsequently given an infusion of 10^6 peripheral blood lymphocytes per kg body weight from twin B to supplement his graft. Over the next 4 months, the patient (twin A) has shown an increase in T-cell numbers, improvement in clinical symptoms, weight gain, and stabilization of his leiomyomas.

RESULTS OF THE CORD BLOOD TRANSPLANTATION STUDY (COBLT): CLINICAL OUTCOMES OF UNRELATED DONOR UMBILICAL CORD BLOOD TRANSPLANTATION IN PEDIATRIC PATIENTS WITH INBORN ERRORS OF METABOLISM

Kurtzberg, J.[1], Carter, S.L.[2], Sahdev, I.[3], Wall, D.[4], Pietryga, D.[5], Wagner, J.E.[6], Kernan, N.A.[7] [1]Duke University Medical Center, Durham, NC; 2/ The EMMES Corporation, Rockville, MD; [3]Schneider Children's Hospital, New Hyde Park, NY; [4]Texas Transplantation Institute, San Antonio, TX; [5]DeVos Children's Hospital, Grand Rapids, MI; [6]University of Minnesota, Minneapolis, MN; [7]Memorial Sloan-Kettering Cancer Center, New York, NY.

The Cord Blood Transplantation Study (COBLT), sponsored by the National Heart, Lung, and Blood Institute, evaluated the outcomes of unrelated donor umbilical cord blood transplantation (UCBT) in 32 patients (56% males; 75% Caucasian) with inborn errors of metabolism. A common protocol was used for the preparative regimen (busulfan, cyclophosphamide, ATG) and GvHD prophylaxis (cyclosporine and steroids). Patients with MPS I Hurler's syndrome (n = 13; 12 reported NEJM 2004:350:1960–9), Hurler-Sheie syndrome (n = 2), Sanfilippo's syndrome (n = 2), I-cell disease (n = 1), Krabbe's disease (n = 7), Tay-Sachs disease (n = 2), and adrenoleukodystrophy (n = 5) with a mean age of 1.83 years were transplanted with an HLA 6/6 (n = 3), 5/6 (n = 14), 4/6 (n = 14), or 3/6 (n = 1) matched unit with a median of $8/6 \times 10^7$ nucleated cells/kg selected from COBLT banks (80%) or other banks (20%). CBUs were screened for enzyme activity to prevent use of a carrier donor. The cumulative incidence of neutrophil engraftment and grade III/IV acute GvHD were 84% in a median of 26 days and 19%, respectively. The probability of survival at 180 days and 2 years was 84%. Seven patients died, 1 before and 6 after transplantation (1 of GvHD with infection, 3 of graft failure, 2 of organ failure, and 1 of hemolytic anemia). The surviving patients with MPS syndromes, Tay-Sachs disease, and Krabbe's disease all stabilized and/or gained skills posttransplantation. One of 5 patients with ALD experienced disease progression, whereas all others stabilized and continue to gain developmental skills. Levels of HLA disparity between recipient and donor determined by retrospective high-resolution DNA typing did not influence engraftment, GvHD, or overall survival. The COBLT study represents the first prospective multicenter trial in children with inborn errors of metabolism undergoing UCBT. UCBT provides rapid access to donors and favorably alters the natural history of the disease and should be considered for patients with metabolic diseases who are eligible for transplantation therapy.

BUSULFAN DOSE ESCALATION TO INCREASE GENE MARKING OF HEMATOPOIETIC STEM CELLS BY LENTIVIRAL VECTORS IN INFANT RHESUS MONKEYS

Kohn, D.B.[1], Kahl, C.A.[1], Lee, C.I.[2], Jiminez, D.F.[2], Choi, C.[1], Pepper, K.A.[1], Petersen, D.[1], Fletcher, M.D.[2], Leapley, A.C.[2], Burns, T.S.[2], Ultsch, M.-N.[2], Tarantal, A.F.[2] [1]Childrens Hospital Los Angeles, Los Angeles, CA; [2]California National Primate Research Center, Davis, CA.

Gene transfer to hematopoietic stem cells (HSCs) using lentiviral vectors may be an attractive approach to treat a variety of diseases. This can be accomplished in the context of an autologous bone marrow transplantation (BMT), where HSC are transduced ex vivo. The myeloablative drug busulfan can then be used to "make space" in the bone marrow compartment, to allow efficient reengraftment of the transduced cells. It is important to identify an optimal busulfan dose that will result in efficient long-term gene marking and have the least toxicity. We performed a lentiviral gene-marking study in infant rhesus macaques using escalating doses of busulfan. Bone marrow (10–15 mL/kg) was harvested from each monkey, followed by a single IV infusion of busulfan over 2 hours in groups of 2–3 using busulfan at 0, 40, 80, 120, and 160 mg/m^2 with dilantin seizure prophylaxis. Peripheral blood busulfan levels were then followed over a period of 4 hours, and the AUC was determined. CD34+ cells were isolated from the harvested bone marrow, cultured for 24 hours in serum-free medium with recombinant cytokines and transduced overnight with an SIV-derived lentiviral vector pseudotyped with the VSV-G glycoprotein. The vector contains a neomycin gene with a mutation in the start codon that abolishes its expression and thus can serve as a nonexpressed marker gene. The next morning, transduced cells were washed and reinfused IV, approximately 48 hours after administration of busulfan. Increasing dosages of busulfan resulted in an increased AUC. However, variability in AUC at each dose level ($\times$ 1.5) was observed, suggesting relatively large interindividual variations in busulfan clearance. At doses of 120 and 160 mg/m^2 busulfan, neutrophil counts transiently dropped under 1000 cells/μL, and platelet counts dropped under 10^5/μL, indicating dose-related neutropenia and thrombocytopenia. Blood chemistries and behavior appeared normal in all animals, and no seizures were observed. Gene marking in mononuclear cells and granulocytes will be measured at monthly intervals by determining the number of integrated proviruses per cell with quantitative PCR. Together, our results suggest that busulfan is safe and has no detectable toxicity at these submyeloablative dosages in infant rhesus monkeys, except for the expected myelosuppressive effects.

We thank ESP Pharma for providing Busulfex for these studies.
