Abstract

Aims/hypothesis—Human islets from type 2 diabetic donors are reportedly 80% deficient in the p21 (Cdc42/Rac)-activated kinase, PAK1. PAK1 is implicated in beta cell function and maintenance of beta cell mass. We questioned the mechanism(s) by which PAK1 deficiency potentially contributes to increased susceptibility to type 2 diabetes.

Methods—Non-diabetic human islets and INS 832/13 beta cells cultured under diabetogenic conditions (i.e. with specific cytokines or under glucolipotoxic [GLT] conditions) were evaluated for changes to PAK1 signalling. Combined effects of PAK1 deficiency with GLT stress were assessed using classic knockout (Pak1⁻/⁻) mice fed a 45% energy from fat/palmitate-based, ‘western’ diet (WD). INS 832/13 cells overexpressing or depleted of PAK1 were also assessed for apoptosis and signalling changes.

Results—Exposure of non-diabetic human islets to diabetic stressors attenuated PAK1 protein levels, concurrent with increased caspase 3 cleavage. WD-fed Pak1 knockout mice exhibited fasting hyperglycaemia and severe glucose intolerance. These mice also failed to mount an insulin secretory response following acute glucose challenge, coinciding with a 43% loss of beta cell mass.
when compared with WD-fed wild-type mice. Pak1 knockout mice had fewer total beta cells per islet, coincident with decreased beta cell proliferation. In INS 832/13 beta cells, PAK1 deficiency combined with GLT exposure heightened beta cell death relative to either condition alone; PAK1 deficiency resulted in decreased extracellular signal-related kinase (ERK) and B cell lymphoma 2 (Bcl2) phosphorylation levels. Conversely, PAK1 overexpression prevented GLT-induced cell death.

Conclusions/interpretation—These findings suggest that PAK1 deficiency may underlie an increased diabetic susceptibility. Discovery of ways to remediate glycaemic dysregulation via altering PAK1 or its downstream effectors offers promising opportunities for disease intervention.

Beta cell mass; Diet-induced obesity; Insulin secretion; PAK1; Prediabetes; Type 2 diabetes

Introduction
At the time of diagnosis of type 2 diabetes, overall islet mass and/or function may be decreased by more than 50% [1–3], suggesting that the progressive degeneration of functional beta cell mass is occurring during the pre-diabetic phase, prior to the development of frank type 2 diabetes. Factors causal in the demise of beta cell function and/or mass in the face of diabetogenic stress are highly sought after.

Previous studies have implicated the serine/threonine p21 (Cdc42/Rac)-activated kinase 1 (PAK1) as a positive and required factor in both beta cell function [4–6] and maintenance of beta cell mass [7, 8]. For example, multiple reports show that Pak1−/− knockout (Pak1 KO) mice fed a standard (non-diabetogenic) diet are glucose intolerant, related to impairments in glucose-stimulated insulin secretion from islets ex vivo [4] and serum insulin release in vivo [5]. Despite this, Pak1 KO mice did not develop fasting hyperglycaemia nor exhibit profound changes in beta cell mass. This contrasts with other reports citing an important role for PAK1 in beta cell proliferation and survival ex vivo [7, 8]. Notably though, the requirement for PAK1 in beta cell proliferation and survival was identified only under conditions of islet stress ex vivo, while the Pak1 KO mice were studied only under standard conditions. It remains possible that alterations in beta cell mass would not manifest in the Pak1 KO mice until challenged with an additional stress to the pancreatic islets, such as chronic consumption of a high-fat diet.

It is established that high-fat diet intake leads to the development of insulin resistance in both humans and animals [9, 10] and that beta cells compensate by increasing insulin release under fasting conditions to quell the ensuing hyperglycaemia, predominantly through expansion of the beta cell mass [11, 12]. However, chronic exposure to saturated fatty acids, such as palmitate, promotes the release of pro-inflammatory cytokines which are cytotoxic to pancreatic beta cells [13, 14]. In addition, saturated fatty acids generate production of reactive oxygen species, leading to endoplasmic reticulum (ER) stress [15], with both processes ultimately leading to beta cell apoptosis. Whether PAK1 is involved in the in vivo compensatory mechanism to maintain euglycaemia in the face of high-fat diet-induced stress, and/or for protecting beta cells from palmitate-induced stress, has remained untested.
Methods

For further details of all experimental protocols please refer to the electronic supplementary material (ESM).

Human islet culture

Pancreatic human islets were obtained through the Integrated Islet Distribution Program (ESM Table 1). Human islets recovered after arrival in Connaught Medical Research Laboratories (CMRL) medium for 2 h, then were handpicked using a green gelatin filter to eliminate residual non-islet material. Human islets were treated with either a cytokine mixture (10 ng/ml TNF-α, 100 ng/ml IFN-γ and 5 ng/ml IL-1 β; all purchased from ProSpec, East Brunswick, NJ, USA) for 72 h, or glucolipotoxic (GLT) mixture (16.7–25 mmol/l glucose plus 0.5 mmol/l palmitate; Sigma, St Louis, MO, USA) for 48 h, in glucose-free RPMI 1640 (Gibco, Carlsbad, CA, USA) medium supplemented with 10% (vol./vol.) FBS (HyClone, South Logan, UT, USA) and 1% (vol./vol.) penicillin/streptomycin (Gibco) for times indicated in the legends, prior to lysis for immunoblot analysis. mRNA was quantified from islets by quantified real-time PCR as described [16].

INS 832/13 cell culture, transient transfection and adenoviral transduction

INS 832/13 cells (gift from C. B. Newgard, Duke University, Durham, NC, USA) (passage 55–80) were grown in RPMI 1640 medium as described [17]. Cells were cultured under GLT conditions for 24 h, transfected with small interfering (si) RNA oligonucleotides (siPak1, cat no. S103082926; siCtrl, cat no. 1027310; Qiagen, Valencia, CA, USA) using RNAiMAX (Invitrogen, Carlsbad, CA, USA), or transduced by infection of adenovirus rat insulin promoter (AdRIP)-hPak1 or AdRIP-Ctrl (Viraquest, North Liberty, IA, USA) at multiplicity of infection (MOI) = 100, and subsequently treated with GLTor vehicle conditions (fatty acid-free BSA) for 2 h prior to harvest for immunoblot or cell death analyses. AdRIP-hPak1 was generated by insertion of the full-length hPak1 cDNA into the Ins2-adenoviral vector (gifted by T. Becker and C. B. Newgard, Duke University, Durham, NC, USA). Adenoviruses were packaged with EGFP to enable visualisation of infection efficiency (Viraquest).

Immunoblotting

Proteins were resolved on 10–12% SDS-PAGE for transfer to Standard PVDF, or polyvinylidene difluoride for LI-COR fluorescence imaging (PVDF/FL; EMD Millipore, Billerica, MA, USA) membranes for immunoblotting using the following antibodies: Rabbit anti-PAK1, phospho extracellular signal-related kinase (ERK1/2)T202/Y204, mouse anti-ERK1/2, B cell lymphoma 2 (Bcl2), and cleaved caspase 3 (Cell Signaling, Danvers, MA, USA), phospho Bcl2S70 and rabbit anti-glyceraldehyde 3-phosphate dehydrogenase (GAPDH) (Abcam, Cambridge, MA, USA), mouse anti-tubulin (Sigma); all used at 1:1000 dilutions. IRDye 680 RD goat anti-mouse and IRDye 800CW goat anti-rabbit (LI-COR, Lincoln, NE, USA) antibodies were used at 1:15,000 dilutions, and goat anti-mouse and anti-rabbit horseradish peroxidase secondary antibodies (Bio-Rad, Irvine, CA, USA) were used at 1:5000 dilutions. All antibodies were validated for specificity based upon predicted molecular weight of immunoreactive band, selective loss of signal using siRNA or gain of
signal using overexpression, and blocking peptides. Immunoreactive bands were visualised with enhanced chemiluminescence (ECL)/Prime (GE Healthcare, Buckinghamshire, UK) and imaged using a Chemi-Doc Touch (Bio-Rad). Phosphorylated and total ERK1/2 blots were imaged using the Odyssey CLx imaging system (LI-COR).

Animals and diets

All animal procedures/protocols were approved by the Indiana University School of Medicine Institutional Animal Care and Use Committee (Indianapolis, IN, USA). Pak1 KO mice are a classic whole-body gene-ablation model maintained on the C57BL/6J genetic background, generated in-house from breeders originating from Jonathan Chernoff (Fox Chase Cancer Center, Philadelphia, PA, USA) [18]. After weaning (at 21 days of age), mice were allowed free access to water and standard chow (2018SX Teklad Global 18% Protein Extruded Rodent Diet, Harlan Laboratories, IN, USA). Mice were group housed until sorted into individual housing after the initial acclimatisation period and the start of the feeding study. All mice were housed under standard housing conditions using paper bedding, on a 12 hr light cycle (7:00 lights on, 19:00 lights off). Paired wild-type (WT) littermates served as controls. Male 6-week old WT and Pak1 KO mice were acclimated to commercially available low-fat diet (LFD, cat no. D01030107, Research Diets, Brunswick, NJ, USA), containing 10% energy from fat, for 2 weeks prior to starting the 45% energy from fat/palmitate-based ‘western’ diet (WD, cat no. D01030108, Research Diets); both pelleted diets.

Serum analytes, i.p. glucose tolerance testing and HOMA-IR

Mice were fasted for 6 h or 16 h prior to i.p. D-glucose (Sigma) injection (2 g/kg body weight) for measurements of serum insulin response and i.p. glucose tolerance tests (IPGTT), respectively. Glucose measurements were sampled from the tail vein using a Hemocue analyzer (Hemocue, Mission Viejo, CA, USA). Serum insulin was quantified using a sensitive rat insulin radio immunoassay kit (EMD Millipore). The homeostasis model for insulin resistance HOMA-IR was calculated according to Matthews et al [19].

Morphometric assessment of islet cell mass

Mouse islet morphology was evaluated using anti-insulin immunohistochemical staining of pancreatic sections as previously described [20]. Percentage of beta cell area was calculated using AxioVision software version LE4.8 (www.zeiss.com/microscopy/en_us/downloads/axiovision; accessed 8 May 2014); beta cell mass was calculated by multiplying percentage of beta cell area with pancreas weight.

Proliferation and immunofluorescent confocal microscopy

Paraffin-embedded pancreatic tissue sections were prepared and assessed as previously described [21]. To assess proliferation, three pancreatic sections at least 100 μm apart were immunostained with rabbit anti-insulin (1: 500 dilution, Santa Cruz Biotechnology, Dallas TX, USA), rabbit antiphospho-Histone 3, Ser10 (pHH3) (1:500 dilution, EMD Millipore) and DAPI-stained (Sigma); pancreatic sections were taken from at least three mice per group. Alexa Fluor 568 goat anti-rabbit IgG (H+L) (1: 500 dilution, Invitrogen) secondary
antibody was used. Sections were scanned using a Nikon TiE inverted microscope (Nikon, Melville, NY, USA). More than 2000 total insulin-positive cells were counted per pancreas. Results were expressed as the percentage of cells positive for all three stains relative to the total number of insulin-positive cells. Guinea pig anti-glucagon (1:500 dilution, EMD Millipore) was used for staining of alpha cells (ESM Fig. 1).

**Cell death assay**

Apoptosis was measured from INS 832/13 cells treated with GLT stress by assessment of DNA fragmentation and histone release from the nucleus using the Cell Death Detection ELISA Plus kit (Roche Applied Science, Indianapolis, IN, USA) [22]. Absorbance was measured at 405 and 490 nm from all samples in duplicate and cell death calculated as per manufacturer’s instructions.

**Statistical analysis**

Data are expressed as the mean± SEM. Statistical comparisons were made by two-tailed Student’s t test or ANOVA, using GraphPad Prism Version 6.0 (GraphPad Software, La Jolla, CA, USA).

**Results**

**Human islets subjected to diabetogenic stressors exhibit reduced PAK1 protein expression**

To determine whether the loss of PAK1 protein reported in type 2 diabetic human islets could be recapitulated in vitro with diabetogenic stressors, islets from non-diabetic human donors were subjected to pro-inflammatory cytokines or GLT conditions. Cytokine treatment decreased PAK1 protein abundance by 23% compared with vehicle-treated islets from the same donor (Fig. 1a). Cytokine action was validated by detection of inducible nitric oxide synthase (iNOS) induction, a reporter of inflammatory stress in islets [23, 24] (data not shown). GLT stress decreased PAK1 by 28%, and significantly increased expression of cleaved caspase 3 (Fig. 1b,c). To obtain enough islets for these paired studies, islets from obese donors were also used (ESM Table 1), and all responded to the diabetogenic stimuli with reduced PAK1. Pak1 mRNA was reduced by 43% from type 2 diabetic islets compared with non-diabetic islets (Fig. 1d). These results indicate that diabetogenic stressors likely contribute to the apoptosis and attenuated PAK1 protein levels seen in type 2 diabetes human islets.

**Pak1 KO mice fed WD exhibit fasting hyperglycaemia with insulin insufficiency**

To first confirm that the WD-diet was obesogenic, food intake and body weight were monitored throughout the 13-week feeding period. Because of the inherent variability in source components for chow, we used a semi-purified, palmitate-based LFD. Although there was no difference in grams of food intake (data not shown), the WD-fed Pak1 KO and WT mice consumed significantly more energy daily and cumulatively (~40% more) than the LFD-fed mice (Fig. 2a). Accordingly, the WD-fed mice showed a larger per cent increase in body weight, with equivalent increases between Pak1 KO and WT mice (Fig. 2b). Adipose tissue was significantly increased in the WD-fed mice vs LFD-fed mice (Table 1). IPGTT
after a 16 h fast showed the WD-fed Pak1 KO mice to have substantially elevated fasting blood glucose concentrations (Fig. 2c,d). LFD-fed mice were heavier and less glucose tolerant than expected, based upon comparisons with chow-fed mice. As our LFD-induced data were similar to another study using these diets [25], this appears to be a feature of the palmitate-containing LFD.

Consistently, after just a 6 h fasting period, WD-fed Pak1 KO mice again displayed elevated fasting blood glucose levels relative to that of WD-fed WT mice (Fig. 3a); the same WD-fed Pak1 KO mice also failed to show increased serum insulin levels upon glucose injection (index: glucose-stimulated/basal insulin levels) (Fig. 3b). By contrast, WD-fed WT mice mounted a substantial insulin response, as previously shown [26]. LFD-fed Pak1 KO or WT mice showed insulin responses similar to chow-fed WT mice (LFD-fed Pak1 KO 1.35 ± 0.15; LFD-fed WT 1.15 ± 0.11; chow-fed WT 1.26 ± 0.17), suggesting that the LFD-diet did not negatively impact islet responsiveness to glucose. WD-fed Pak1 KO mice show increased insulin resistance compared with WD-fed WT mice, as calculated by HOMA-IR (Fig. 3c). These phenotypic data suggest that the WD-fed Pak1 KO mice were unable to mount a sufficient insulin response to manage the elevated glucose load induced by WD-feeding.

**Pak1 KO mice show no WD-induced gain in beta cell mass**

Given the insulin insufficiency seen in the WD-fed Pak1 KO sera, the corresponding pancreases were evaluated ex vivo for changes in beta cell mass relative to LFD- and WD-fed WT mice. WD-fed Pak1 KO islet beta cell area was visibly diminished relative to WD-fed WT mice (Fig. 4a). At ~0.83% beta cell area, the WD-fed WT beta cell area exceeded the 0.67% beta cell area of the LFD-fed WT mouse pancreas (Fig. 4b, n = 3 pancreases per group, p = 0.054). Beta cell area was reduced to ~0.45% in WD-fed Pak1 KO mouse islets (red bar), a significant 46% loss relative to the WD-fed WT mice. Calculating beta cell mass, which takes into account total pancreas weight, WD-fed Pak1 KO mice were 43% deficient, relative to WD-fed WT mass (Fig. 4c). Glucagon-staining was visibly similar among all groups (ESM Fig. 1). Thus, unlike the WT mice, the Pak1 KO mice showed no WD-induced gain in beta cell area or mass.

**Decreased beta cell replication in WD-fed Pak1 KO mice**

To determine if loss of beta cell mass in WD-fed Pak1 KO mice was related to defects in replication, pHH3 staining was evaluated [26]. While pHH3-stained cells were detected in insulin-stained islet cells from WD-fed WT mice, no pHH3-positive cells were seen in an equivalent number of beta cells from WD-fed Pak1 KO mice (Fig. 5a,b). Moreover, while WD-fed Pak1 KO mice had 35% fewer insulin-staining beta cells per islet (Fig. 5c), the number of islets was similar among all groups (Fig. 5d). These results suggest that PAK1 is required in the WD-induced beta cell replication.

**PAK1 deficiency exacerbates the effects of glucolipotoxicity upon beta cell demise**

INS 832/13 cells were exposed to GLT stress as a means to interrogate the mechanism(s) underlying the beta cell mass differences in the mice. Prior reports of PAK1 signalling downstream to ERK were tested for involvement [4, 6]. After 24 h of GLT treatment, INS
832/13 cells exhibited substantial cell death, as determined by the presence of cytosolic nucleosomal fragments [22] (Fig. 6a), and a sevenfold increase in cleaved caspase 3 in GLT-treated cells (Fig. 6b). Concurrent with this, cells had 30% less PKA1 protein, and >60% reductions in phosphorylated ERK1/2 (pERK1/2), a downstream target of PKA1 in beta cells, and pBcl2, an anti-apoptotic factor (Fig. 6b). These results suggest links between PKA1 abundance and ERK1/2 and Bcl2 signalling in GLT-induced beta cell stress.

To determine whether PKA1 depletion exacerbates the effects of GLT upon apoptosis, perhaps in an additive manner, the GLT exposure time was limited to just 2 h in cells transfected with scrambled (Ctrl) or Pak1 siRNAs. GLT exposure for just 2 h did not significantly reduce PKA1 protein levels, permitting separation of GLT effects from PKA1 depletion. The combined effect of Pak1 siRNA with 2 h GLT stress exerted a significant increase in cell death over that of depletion or GLT stress alone (Fig. 7a). PKA1 depletion resulted in reduced levels of pERK1/2 and pBcl2 (Fig. 7b).

Consistent with a role in cell survival/anti-apoptosis, PKA1 overexpression protected cells from GLT-induced cell death (Fig. 8a). PKA1 overexpression increased pERK1/2 levels only slightly (Fig. 8b), perhaps suggesting that ERK1/2 phosphorylation was maximised under our serum-containing cell culture conditions (serum contains growth factors that activate ERK1/2). PKA1 overexpression significantly increased levels of phosphorylated Bcl2.

**Discussion**

In this report we demonstrate that increased PKA1 abundance can protect beta cells against GLT-induced cell death, and that this is linked through phosphorylation of the anti-apoptotic factor Bcl2. Our studies suggest that in the islet beta cell, chronic exposure to GLT stress impairs PKA1 abundance, coordinate with attenuated ERK and Bcl2 signalling, and increased cell death. In human islets, chronic GLT stress also reduced PKA1 protein and increased cleaved caspase 3 expression. Modelling GLT stress in vivo, Pak1 KO mice fed a palmitate-rich western diet (WD-fed Pak1 KO) displayed significant fasting hyperglycaemia and loss of beta cell mass in just 10 weeks. As such, PKA1 deficiency may underlie an increased diabetic susceptibility.

Since the islets of the WD-fed Pak1 KO mice also had decreased beta cell proliferation relative to WD-fed WT mice, PKA1 may play multiple roles in the process of beta cell mass expansion. The apparent additivity of short-term/acute GLT stress with PKA1 knockdown could suggest that GLT induces an early PKA1-independent signal that is insufficient to evoke cell death; since PKA1 levels are un-impacted by this, the anti-apoptotic mechanism is maintained. Indeed, acute GLT treatment impacts $K_{\text{ATP}}$ and $Ca^{2+}$ channel functions in beta cells without inducing apoptosis [27, 28]. However, once GLT exposure is prolonged, then PKA1 is decreased, and ERK1/2 and Bcl2 are left unchecked to allow apoptosis. Beyond the beta cell, PKA1 has been demonstrated to downregulate additional pro-apoptotic factors, such as forkhead box in rhabdomyosarcoma (FKHR; also known as forkhead box O1 [FOXO1]) and Bcl-2-interacting mediator of cell death (BimL) [29–31]. Given the possibility that apoptosis effects in clonal beta cells may not fully account for the differences in mouse beta cell mass observed, beta cell replication was also evaluated, using mouse
pancreases. Our data indicated that PAK1 may be important for beta cell replication and survival. Indeed, PAK1 is known to participate in cell cycle progression and mitosis via regulating various effectors, such as Aurora-A [32], Polo-like kinase 1 [33] and cyclin-D1 [34] in other cell types.

Chronically elevated levels of NEFA, principally saturated fatty acids, exert deleterious effects on islet beta cells. In vitro, saturated NEFA such as palmitate increase basal insulin secretion, decrease glucose-stimulated insulin secretion [35–37] and increase beta cell death [22, 38, 39]. Palmitate causes these detrimental effects through multiple mechanisms, such as increasing reactive oxygen species, ceramide, and excessive nitric oxide production, as well as activation of ER stress pathways [40, 41]. In vivo, healthy beta cells have the capability to adapt to elevated serum NEFA levels through mechanisms that are not completely understood. However, in genetically pre-disposed beta cells, glucolipotoxicity eventually results in beta cell decompensation and dysfunction and ultimately beta cell failure [42, 43]; our findings support the concept that PAK1 depletion represents a new type of genetic predisposition. The importance of PAK1 in maintaining functional beta cell mass during dietary stress becomes clinically relevant when considering that PAK1 protein levels in type 2 diabetic human islets are reduced by ~80% compared with non-diabetic controls [4] and that the human Pak1 gene is located in the type 2 diabetes susceptibility locus on Chromosome 11 [44, 45]. While much more needs to be known to determine whether Pak1 actually confers the diabetes risk at this site and whether the diabetes risk allele even results in decreased PAK1 expression, Pak1 mRNA was reduced by 43% in type 2 diabetic compared with non-diabetic and non-obese donor islets. The most appropriate way to determine whether Pak1 confers diabetes risk at the sites mentioned may be to examine Pak1 mRNA and protein in islets from donors (low BMI, obese and type 2 diabetic) known to carry the risk allele.

The palmitate-based diet was chosen to mimic the palmitate-rich fast-food diet prevalent in western society. This revealed that WD-fed WT could maintain the glucose tolerance profile of the LFD-fed WT mice through upregulation of their functional beta cell mass (increased insulin release and beta cell expansion). However, that the blood glucose levels remained >16.65 mmol/l at 2 h after glucose injection is reminiscent of a peripheral insulin resistant phenotype, suggesting that the palmitate-enriched LFD-diet may have generally impacted glucose homeostasis. This concept is supported by prior analyses of WT vs Pak1 KO mice fed standard chow, wherein WT mice were glucose tolerant and the Pak1 KO mice were intolerant [4, 5]. Moreover, in the current study, LFD-fed WT and Pak1 KO mice weighed 20% more than age-matched chow-fed mice after just 13 weeks of feeding (p < 0.05), suggesting that the palmitate-based fat source prompted obesity and insulin resistance. Therefore, while on the LFD-diet, it is possible that insulin resistance and subsequent glucose intolerance induced by increased weight-gain alone masked the underlying defects arising from the PAK1 deficiency.

In this whole-body Pak1 KO model, input from tissues/organs beyond the islet beta cell may have contributed to the fasting hyperglycaemia and glucose intolerance of the WD-fed Pak1 KO mice. For example, in skeletal muscle Pak1 is required for the translocation of GLUT4 vesicles to the plasma membrane to facilitate glucose clearance, and chow-fed Pak1 KO
mice have been shown to display defects in this process [4]. Additionally, a defect in GLP-1 production and secretion has been reported both in Pak1 KO mice [5, 46] and PAK1-depleted GLP-1-secreting L cells [47]. As GLP-1 is involved in enhancing glucose-stimulated insulin secretion, increasing insulin biosynthesis, and promoting maintenance of beta cell mass [48, 49], as well as processes external to beta cell [50, 51], it is possible that depressed GLP-1 secretion/signalling is contributing to the severe glucose intolerant phenotype of the WD-fed Pak1 KO mice. Along these same lines, it has been reported that activation of the GLP-1R-signalling pathway in the liver rescues the impaired pyruvate tolerance observed in aged Pak1 KO mice [46]. Clarifying the role of PAK1 in the process of beta cell compensatory mechanisms will thus require the study of beta cell-specific Pak1 KO mice.

In summary, we have demonstrated the requirement of PAK1 in the adaptation of the beta cell to the metabolic stress of a palmitate-rich western-style diet. These studies additionally suggest that inflammatory- or GLT-stressors carry the capacity to reduce PAK1 protein levels in human islets. PAK1 may be a critical factor to target as a means to rescue/enhance beta cell mass in response to the stresses encountered during the development of pre- and type 2 diabetes.

Chronic GLT-induced stress reduces PAK1 abundance concurrent with reduced ERK and Bcl2 phosphorylation. INS 832/13 cells were subjected to GLT for 24 h and (a) cell death was determined by ELISA. (b) Resultant lysates were assessed for PAK1 content, phosphorylated (p) and total (t) forms of ERK and Bcl2, and cleaved caspase 3 by immunoblot quantification. The bar graph represents the average ± SEM, with vehicle-treated lysate bands in each of five independent cell passage experiments set equal to 1 and GLT-treated protein levels normalised thereto. *p < 0.05
Fig. 7.
Combined effects of PAK1 depletion and acute glucolipotoxicity upon beta cell death. INS 832/13 cells transfected with Pak1 siRNA or control (Ctrl) siRNA were incubated for 46 h prior to GLT exposure for 2 h and (a) cell death was determined by ELISA ($n = 5–6$; abs, absorbance). (b) Resultant lysates were assessed for PAK1 content and phosphorylated (p) and total (t) forms of ERK and Bcl2. The bar graphs represent the average ± SEM, with siCtrl/vehicle-treated lysate bands in each of three independent cell passage experiments set equal to 1 and remaining treatment group protein levels normalised thereto. *$p < 0.05$, **$p < 0.01$
Fig. 8.
PAK1 overexpression protects against acute GLT-induced cell death. INS 832/13 cells were transduced to overexpress human PAK1 using AdRIP-hPAK1 or AdRIP-Ctrl for 46 h prior to GLT exposure for 2 h and (a) cell death was determined by ELISA ($n = 3$; abs, absorbance). (b) Resultant lysates were assessed for PAK1 content, phosphorylated (p) and total (t) forms of ERK and Bcl2 by immunoblot quantification. The bar graph represents the average ± SEM, with AdRIP-hPak1/vehicle-treated lysate bands in each of three independent cell passage experiments set equal to 1 and remaining treatment group protein levels normalised thereto. *$p < 0.05$, **$p < 0.01$; ***$p < 0.001$

</table>

Data represent the average ± SEM.

Weights were collected after 13 weeks of feeding the diets indicated, for determination of variables shown. Statistically significant differences were detected by two-way ANOVA using a Tukey’s multiple comparison test:

<sup>a</sup> WT-WD vs Pak1 KO-LFD;
<sup>b</sup> WT-WD vs WT-LFD;
<sup>c</sup> Pak1 KO-WD vs Pak1 KO-LFD;
<sup>d</sup> Pak1 KO-WD vs WT-LFD.
