Abstract

Background/Aims—Patients with chronic kidney disease mineral and bone disorder (CKD-MBD) have a significantly higher vertebral and non-vertebral fracture risk than the general population. Several preclinical models have documented altered skeletal properties in long bones, but few data exist for vertebral bone. The goal of this study was to examine the effects of progressive CKD on vertebral bone structure and mechanics and to determine the effects of treatment with either bisphosphonates or anti-sclerostin antibody in groups of animals with high or low PTH.

Methods—Animals with progressive kidney disease were left untreated, treated with calcium to lower PTH, zoledronic acid to lower remodeling without affecting PTH, anti-sclerostin antibody, or anti-sclerostin antibody plus calcium. Non-diseased, untreated littermates served as controls. Vertebral bone morphology (trabecular and cortical) and mechanical properties (structural and material-level) were assessed at 35 weeks of age by microCT and mechanical testing, respectively.

Results—CKD with high PTH resulted in 6-fold higher bone formation rate, significant reductions in the amount of trabecular and cortical bone, and compromised whole bone mechanical properties in the vertebra compared to normal animals. Treatments that reduced bone remodeling were effective in normalizing vertebral structure and mechanical properties only if the treatment reduced serum PTH. Similarly, treatment with anti-sclerostin antibody was effective in enhancing bone mass and mechanical properties but only if combined with PTH-suppressive treatment.

The manuscript will undergo copyediting, typesetting, and review of the resulting proof before it is published in its final citable form. Please note that during the production process errors may be discovered which could affect the content, and all legal disclaimers that apply to the journal persist.
Conclusions—CKD significantly altered both cortical and trabecular bone properties in the vertebra resulting in compromised mechanical properties and these changes can be normalized by interventions that involve reductions in PTH levels.

INTRODUCTION

Patients with chronic kidney disease—mineral and bone disorder (CKD-MBD) have a significantly higher fracture risk than the general population [1-3]. This population also displays differences in fracture rates between long bones and vertebrae [3], suggesting that these two skeletal sites may be differentially affected by the disease. A study of Japanese men on dialysis who underwent screening lumbar spine imaging studies demonstrated that 20.9% of prevalent dialysis patients had evidence of spine fractures [4]. High resolution CT data have revealed significant increases in cortical porosity in the distal limbs with variable responses in trabecular bone [5]. Because vertebral elements are primarily composed of trabecular bone, the influence of secondary hyperparathyroidism on these sites could be potentially different than in long bone cortices [6]. Furthermore, the thin cortical shell of the vertebrae bears nearly 50% of the load [7]; thus, cortical bone changes at this site would also have dramatic effects on mechanical properties and fracture risk.

Several animal models of CKD have revealed significant detriments in the biomechanical properties of long bones [8-10]. For example, rodent models indicate that animals with CKD exhibit lower strength and stiffness compared to their normal counterparts [11-13]. While much of the decline in mechanical integrity can be attributed to structural changes resulting from high parathyroid hormone (PTH) and high turnover rates, recent studies indicate that bone quality also plays a role [9]. Unfortunately, vertebral bone in CKD models has yet to be examined at any of these levels. The goal of this study was to assess the effects of progressive CKD on vertebral bone structure and mechanics and to determine the effects of treatment with either anti-remodeling medications (bisphosphonates) or anabolic treatments (anti-sclerostin antibody). We hypothesized that a significant phenotype would exist in the vertebrae of CKD animals and that treatment would restore structural mechanical properties but not the material-level mechanical properties.

METHODS

Animal model

Cy/+ rats exhibit the progressive onset of polycystic kidney disease due to transmission of an autosomal dominant missense mutation in the geneAnks6, which codes for the protein SamCystin [14-16]. Anks6 has been shown to be important in childhood recessive cystic kidney disease although heterozygote parents have no manifestations [17-19]. The course of kidney disease progression in the Cy/+ rats parallels the course of human CKD-Mineral Bone Disorder (CKD-MBD) [16]. A colony of these animals is maintained at the Indiana...
University School of Medicine. All procedures were reviewed and approved by the Indiana University School of Medicine Institutional Animal Care and Use Committee.

Experimental design

The animals described in this work were part of a large experiment that included numerous treatment and control groups. Male Cy/+ rats began the study at 25 weeks of age at which time animals were fed a casein-based diet (Purina AIN-76A, Purina Animal Nutrition, Shreevport, LA, USA); 0.53% Ca and 0.56% P) in order to accentuate the disease. Subsets of Cy/+ animals were divided into the following groups (Figure 1):

Controls (CKD)—These animals were left untreated. Based on the previously described phenotype these animals have high PTH and high bone turnover [11,20].

Calcium (CKD-Ca)—These animals were treated with calcium-supplemented water (3%) starting at 30 weeks of age. Based on the previously described phenotype these animals have low PTH and low bone turnover [11,20].

Zoledronic acid (CKD-Z)—These animals were treated with zoledronic acid (20 ug/kg/BW as a single subcutaneous injection at 30 weeks of age). Based on the previously described phenotype these animals have high PTH and low bone turnover [11,20]. Zoledronic acid was chosen as a representative bisphosphonate to study in CKD as it has an infrequent dosing schedule (1x per year in post-menopausal osteoporosis treatment) and has high affinity for the bone matrix thus likely to impart persistent treatment effects.

Anti-sclerostin antibody (CKD-SCL)—These animals were treated with anti-sclerostin antibody (Scl-Ab; 100 mg/kg/week starting at 30 weeks of age). Scl-AB was provided by Novartis Institutes for BioMedical Research, Novartis Pharma AG. Based on the previously described phenotype these animals have high PTH and high bone turnover [11,20]. Anti-sclerostin antibody was chosen as it has emerged as a promising potential anabolic drug treatment.

Anti-sclerostin antibody plus calcium (CKD-SCL-Ca): These animals were treated with anti-sclerostin antibody and calcium (3% in water). Based on the previously described phenotype these animals have low PTH and high bone turnover [11,20].

Normal (NL)—A group of non-diseased male littermates were untreated.

All animals were sacrificed at 35 weeks of age. For all experiments, serum biochemistries and long bone phenotypes have been previously reported in various publications, yet are repeated in the results when deemed necessary [11,13,20].

Dynamic Histomorphometry

In order to describe the basal remodeling phenotype of the vertebra in NL and CKD animals, the third lumbar vertebra of animals from a separate experiment [13] was processed for undecalcified histomorphometry. The vertebral arch was removed, and the body was embedded in PMMA for sectioning. Thin sections (~4 um) were cut and left unstained for
analysis. Briefly, a 2 mm² region of interest in the caudal region of the vertebra cranial to the growth plate was used for the analysis. Primary measurements were obtained and used for the derived parameters mineralizing surface/bone surface (MS/BS), mineral apposition rate (MAR), and bone formation rate/bone surface (BFR) as previously described [11] using standard nomenclature [21].

**Computed tomography**

Morphological parameters of the fourth lumbar vertebrae from all experiments were assessed using high-resolution micro-CT (Skyscan 1172). Bones were wrapped in parafilm to prevent drying during the scanning. Scans were obtained using an x-ray source, set at 60kV with a 12-μm pixel size.

Images were reconstructed and analyzed using standard Skyscan software (NRecon and CTAn, respectively). Trabecular regions of interest were manually drawn to isolate it from the cortical bone between the cranial and caudal growth plates. Bone volume/tissue volume (BV/TV), trabecular number (Tb.N), and trabecular thickness (Tb.Th) were computed according to previously published recommendations [22]. A single slice at 75% of the total vertebral length (from cranial to caudal) was used for the assessment of cortical thickness as this represents a region devoid of zygapophyseal attachment. Bone area was assessed at 25%, 50%, and 75% of the total height for normalization of mechanical properties.

**Mechanics**

Structural mechanical properties and apparent material properties were assessed by uniaxial compression testing of the L4 vertebra from all 3 experiments. At harvest, the vertebrae were wrapped in saline-soaked gauze and frozen at -20 degrees. Bone height was assessed from microCT images. Prior to mechanical testing, the vertebral arch and the endplates were removed using an Isomet saw in order to create parallel surfaces (beneath the growth plates) for compression testing. Samples were loaded in displacement control at 0.5 mm/min. Load and displacement data were collected at 10 Hz and converted to stress and strain data from the initial sample height and the average bone area of 3 slices (25%, 50%, and 75% slices of the initial height of the sample). Load-displacement data were used to compute ultimate load, stiffness, and energy to failure (with failure defined as the point ultimate load first drops off), while apparent material properties were derived from the stress-strain data and used to calculate ultimate stress, elastic modulus, and toughness to the point of the ultimate stress [23].

**Statistics**

Statistics were carried out on select groups in order to answer a priori questions related to 1) basal phenotype of the CKD model, 2) the effects of anti-remodeling treatment with and without altered PTH levels, and 3) the effects of anabolic treatment with and without altered PTH levels (Figure 1). Comparisons were made using student's t-tests or one-way ANOVA followed by Fisher protected least significant difference post hoc tests. P values were set at < 0.05. Data are reported as means and standard deviations.

RESULTS

CKD with high PTH leads to high remodeling rate, bone loss, and compromised structural and material mechanical properties

Select biochemistries and animal body weights are presented in Table 1. PTH levels in the CKD animals were over 10-fold higher than normal animals (Figure 1). Histological assessment of vertebral trabecular bone revealed that mineral apposition rate was more than doubled (NL = 1.21; CKD = 2.98), mineralizing surface/bone surface was 2.5x higher (NL = 10.5; CKD = 24.5) and bone formation was 6-fold higher in CKD animals compared to normal (Figure 2A). Thus, the untreated CKD model is one of high PTH and high remodeling as illustrated in the photomicrographs (Figure 2F-G).

Vertebral microCT analyses showed that cortical thickness (−17%) and trabecular BV/TV (−30%) were both significantly lower in CKD compared to normal (Figure 2B&C and H-K; Table 2). Ultimate force (−34%), stiffness (−21%), and energy to failure (−42%) were all significantly lower in CKD compared to NL (Figure 2D &E; Table 2). Calculation of material properties revealed significant lower ultimate stress (−24%) and toughness (−34%), but not modulus, in CKD animals (Table 2).

Low turnover with suppression of PTH normalizes vertebral bone morphology and mechanical properties

CKD animals treated with calcium (CKD-Ca), which reduced PTH and tibial bone suppresses bone remodeling [20], had similar vertebral cortical thickness but significantly higher trabecular BV/TV (+15%), compared to normal, non-diseased animals (Figure 3A&B; Table 2). Cortical thickness and BV/TV in CKD-Ca were both significantly higher than CKD animals. Ultimate load and energy to failure of CKD-Ca vertebreae were equivalent to NL (and higher than CKD) with the exception of stiffness, which was not significantly different among groups (Figure 3C&D; Table 2). Ultimate stress, modulus, and toughness of CKD-Ca were all equal or higher than NL animals (Table 2) and all higher than CKD.

In animals treated with zoledronic acid (CKD-Z), which suppresses bone remodeling without lowering PTH [20], the results were in stark contrast to CKD-Ca. Cortical thickness (−16%) and trabecular BV/TV (−18%) were both significantly lower than NL and CKD-Ca (Figure 3A&B; Table 2). Ultimate force (−28%) was significantly lower in CKD-Z compared to NL, while stiffness and energy to failure were not different (Figure 3C&D; Table 2). Ultimate stress and modulus were lower than NL, while all three material properties were significantly lower than CKD-Ca (Table 2).

High turnover with suppression of PTH, but not without, enhances vertebral morphology and vertebral mechanical properties

CKD animals with high PTH treated with anti-sclerostin antibody, previously shown to not alter PTH or bone remodeling relative to untreated CKD [20], had significantly lower cortical thickness (−11%), trabecular bone volume (−27%), and ultimate load (−32%), and stiffness (−54%) compared to NL (Figure 4A-C; Table 2). Ultimate stress and modulus
were both significantly lower than NL (Table 2). Overall, the vertebral phenotype of the CKD-Scl animals closely resembled the CKD animals with the exception of stiffness/modulus (which were lower) and energy to failure/toughness (which were higher).

When anti-sclerostin antibody was combined with calcium (CKD-SCL-Ca), effectively reducing PTH and normalizing remodeling to NL levels [20], the results were dramatically different than anti-sclerostin alone. Cortical thickness was equivalent to NL animals while BV/TV (+15%) was significantly higher than NL, equivalent to CKD-Ca (Figure 4A&B; Table 2). Ultimate load (+25%) was significantly higher than all other treatments while energy to failure (+51%) was significantly higher than all treatments except CKD-Ca (Figure 4C&D; Table 2) while material properties were all comparable to NL animals, higher than most other groups (Table 2).

DISCUSSION

The goal of this study was to assess the vertebral phenotype of CKD given the high clinical risk of vertebral fracture in this patient population [4,24] and the paucity of preclinical data on spine changes with CKD. In this progressive CKD animal model we found 1) elevations in endogenous PTH were associated with high turnover bone disease, compromised cortical and trabecular bone mass, and reduced mechanical properties (both structural and material) of the vertebra and 2) treatment of the vertebral phenotype with either anti-resorptive or anabolic therapies was only effective, from a mechanical standpoint, if serum PTH was reduced.

CKD patients have a higher risk of fracture compared to non-CKD patients [25]. Changes to long bones have been the central focus of most clinical work due to the advances in high-resolution peripheral imaging which has yielded rich information regarding changes to cortical/trabecular bone. Most notably these studies have shown that changes to the cortical bone are dramatic [5] and more severe than are typically observed with post-menopausal osteoporosis (which affects trabecular bone to a greater degree, at least initially). The risk of vertebral fracture is also increased in CKD patients [4,24,26,27], yet little information exists regarding changes to bone mass/architecture at this site. The distribution of cortical and trabecular bone in the vertebra differs significantly from long bones and although cortical bone still contributes to the mechanical integrity of the spine [7], it is possible that the intricacies of bone loss may differ from long bones. The paucity of clinical studies focused on the spine is understandable due to imaging limitations. However for reasons that are unclear this extends to preclinical studies where few studies have examined vertebral bone [8].

The current study showed dramatic loss of trabecular bone mass and thinning of the cortical shell in the vertebra of CKD animals with high PTH, irrespective of whether they were untreated, treated with bisphosphonate, or treated with anti-sclerostin antibody. These results contrast with the long bone phenotype of these same animals where cortical porosity was higher than normal but trabecular BV/TV was not positively affected in high PTH animals treated with these agents [20] (Figure 5). In high-PTH CKD animals, both vertebra and proximal tibia trabecular bone had high bone formation rate, suggesting that simply having
high remodeling does not explain the divergent trabecular BV/TV. In conditions where PTH is normalized, using calcium supplementation, both trabecular and cortical bone area normalized (or enhanced) compared to non-CKD animals. While additional work will be necessary to elucidate why long bones and vertebra differentially respond in the setting of CKD, it raises concern about the clinical use of iliac crest bone biopsies as an assessment of trabecular bone, especially in assessing bone volume [28-32]. It may be that iliac crest biopsy changes are more reflective of long bone trabecular responses than they are of the vertebra. This is supported by an previous study in renal transplant patients that showed no change in iliac crest biopsy cancellous BV/TV after 6 months while spine, but not radius, BMD changed significantly during this same time frame [33].

The structural mechanical phenotype of the vertebrae closely follows that of the long bones in these same animals, where compromised ultimate load, stiffness, and energy to fracture existed in animals with high PTH, even if treated with the potent anti-remodeling agent zoledronic acid or the potent anabolic anti-sclerostin antibody [20]. Treatment with calcium, to lower PTH, normalized vertebra ultimate load and energy to failure, both parameters that have functional significance for fracture resistance [34]. In animals where reduced PTH was combined with the anabolic intervention of anti-sclerostin antibody, both ultimate load and energy to failure exceeded values from normal animals (Figure 3). Enhanced vertebral mechanical properties have similarly been observed in ovariectomized animals treated with anti-sclerostin antibody [35]. Yet the response in these CKD animals differs from the long bone, where calcium plus anti-sclerostin antibody normalized, but did not significantly increase, ultimate load relative to NL animals [20] (Figure 5). These data illustrate the importance of normalizing PTH in treating the vertebral mechanical phenotype of CKD and highlight that anabolic therapy can be more effective at sites that have large proportions of both cortical and trabecular bone (such as the spine and femoral neck).

Structural mechanical properties are determined by bone mass, geometry/architecture, and the mechanical properties of the material (sometimes referred to as bone quality) [36]. Compromised bone mass and architecture are widely appreciated in CKD while the changes in bone quality have only recently begun to be explored [37,38]. We have shown, using both calculations of material properties from whole bone tests [11,13,20] as well as by more direct measures [9] that long bones of CKD animals have reduced properties at the material level. This is associated with changes to both collagen and matrix hydration [39] although a cause-effect relationship has not been elucidated. The current work shows that high turnover, high PTH CKD disease compromises the mechanical properties of the material – as both ultimate stress and toughness, are significantly lower than NL. This means that not only does the vertebra have lower bone mass but the bone mass that exists has compromised material properties relative to normal. Controlling PTH levels normalizes the material properties – contributing to the normalization of whole bone mechanical properties while treatments that did not affect PTH (zoledronic acid and anti-sclerostin antibody alone) had mixed effects on material properties.

The current experiment utilized zoledronate as a representative bisphosphonate to study in the setting of CKD. It is well accepted that each bisphosphonate has different biophysical properties of mineral binding strength and affinity to hydroxyapatite [40]. These properties
affect many of the physical and physiological actions of the drugs including drug localization, speed of onset, degree of remodeling suppression, and speed of withdrawal [41]. It is unclear whether a different bisphosphonate would be more beneficial in the setting of CKD. Zoledronate has long lasting effects on remodeling suppression, more than 5 years following a single dose [42,43] meaning that it would be difficult to washout the effect if needed. Lower affinity bisphosphonates, such as risedronate, have been shown to washout more rapidly than alendronate (a high affinity agent) [44] suggesting it may be more appropriate in the setting of CKD if concerns exist about treatment washout duration. More work with bisphosphonates are necessary to understand the details of their effects on bone, as well as the safety on the kidney, in the setting of CKD. It is possible that there is diversity in the renal safety among the bisphosphonates but additional work is needed in this area [45]. In addition, despite efficacy of calcium in lowering PTH and improving serum calcium, in our previous publications we have observed increased arterial calcification suggesting that both efficacy and safety should be considered with any interventions.

In conclusion, the present study provides a clear picture of how progressive CKD, with and without interventions, affects vertebral bone properties. Since CKD-associated bone disease and fracture risk is significant at this site, it is important to recognize that response to treatment differs from long bones. Despite these differences, what is clear from this study is that reducing PTH is fundamental in normalizing mechanical properties. As such, any anti-resorptive or anabolic bone therapies utilized in CKD should be examined in combination with therapies that suppress PTH (such as calcitriol and 1,25 vitamin D analogs and calcimimetics).

ACKNOWLEDGEMENTS

This work was supported by NIH grant AR058005 and funding from Novartis to SMM, NIH grant DK10093 to CLN and IUSM-CTSI training grant TR001107 to CLN. The authors would like to thank Dr. Michaela Kneissel for providing the anti-sclerostin antibody and input on dosing.

HIGHLIGHTS

- An animal model of progressive kidney disease was studied to understand the effects of disease/treatment on spine properties.

- CKD negatively affected cortical and trabecular properties leading to compromised mechanical properties.

- Pharmacological treatments were effective in normalizing vertebral structure and mechanical properties only if the treatment reduced serum PTH.
