## ACKNOWLEDGMENTS

This project would not have been possible without the guidance and support of many people including faculty, advisors, colleagues, friends and family. I am extremely grateful to my advisor, Dr. Sean Mooney, for welcoming me into his laboratory as a graduate student, and for providing, not only computing resources, but continued support, suggestions, and guidance as, what started out as an independent study project, grew into what became this thesis. I extend my sincere appreciation to Dr. Giselle Knudsen, an honorary member of my thesis committee, for the original project inspiration, for her enthusiastic encouragement, insight, and direction throughout the project, and for her thoughtful review of this thesis. I would like also like to extend a heartfelt thank you to Dr. William Sullivan and Dr. Xiaoman Li for their willingness to lend their time to reviewing my thesis and for the insightful feedback they provided. For statistical expertise and support I would like to extend my deepest appreciation to Dr. Eunseog Eun. Thank you also to Dr. Snehasis Mukhopadhyay for advice provided in the early stages of this work. For assistance with various software installations, I would like to thank Brandon Peters and Dustin Reynolds, and for assistance early in the project with BioPerl, I would like to thank Jessica Dantzer.

It is my pleasure to thank my employer, Dow AgroSciences LLC, Indianapolis, IN, for providing computing resources and funding the majority of my graduate work. My sincere gratitude is extended to Dr. Neil Kirby of Dow AgroSciences for his flexibility and support throughout my graduate studies. Also, I would like to thank my colleagues Dr. Ignacio Larrinua, for consulting on various issues, and Mindi Dippold, for her assistance with Perl.

Finally, I am very grateful to my friends and family, and especially Terry, for their support and encouragement throughout this journey.

## ABSTRACT

Amy L. Schmidbauer

### MINING FOR CONSERVED MOTIFS AND SIGNIFICANT FUNCTIONS IN *S. MANSONI* CERCARIAL SECRETIONS

Schistosomiasis is a disease caused by a parasitic flatworm of the genus *Schistosoma*. It infects an estimated 200 million people and 165 million head of livestock worldwide. There is medical interest in characterizing the parasitic proteins that interact with the human host for either the development of vaccines or the identification of drug targets. The cercarial secretome and adult tegument sub-proteome of *S. mansoni* have both been recently published (Knudsen, Medzihradszky *et al.* 2005) (van Balkom, van Gestel *et al.* 2005). As secretome proteins are secreted extracellularly, and tegument sub-proteome proteins are anchored in the cellular membrane, we hypothesize that both sets of proteins employ similar secretion machinery and mechanisms. Motivated by the discovery in the malarian parasite, *Plasmodium falciparum*, of conserved sequence motifs that are required for export downstream of N-terminal signal sequences (Hiller, Bhattacharjee *et al.* 2004), *S. mansoni* secretory and tegumental proteins were analyzed for conserved motifs using recursive iterations of MEME and MAST. To compliment the conserved motif analysis, an automated workflow to process InterProScan functional domain and GO annotation data, that employs statistical methods for determining significant functions, was developed. A conserved motif, enriched in the mechanically-induced vesicle secretion proteins, was elucidated and insight was gained into both the functions of proteins found to contain the motif, as well as the effects of different cercarial secretion induction methods. A hypothesis of the secretion model employed by the invading parasite was generated.

## GLOSSARY

**1D SDS PAGE-** One dimensional sodium dodecyl sulphate polyacrylamide gel electrophoresis. A technique for separating large numbers of proteins by loading them onto a gel and applying an electric current.

**2D gel electrophoresis-** Two dimensional polyacrylamide gel electrophoresis. A technique for separating large numbers of proteins by loading them onto a gel, applying an electric current to separate by isoelectric point, then, in the perpendicular direction, separating them by molecular weight.

**acetabular glands-** *S. mansoni* possesses 2 sets of acetabular glands, one set posterior and one set anterior to the acetabulum (ventral sucker), which produce mucus and enzymes that are important in skin penetration.

**acetabulum-** Ventral sucker of *S. mansoni*. Plays an active role in skin exploration and penetration.

**BAC-** Bacterial artificial chromosome. A DNA construct, based on a fertility plasmid, used for transforming and cloning in bacteria, usually *E. coli*. Its usual insert size is 150 kbp, with a range from 100 to 300 kbp.

**Bayes optimal classifier-** Statistical classifier for predicting class membership probabilities, based on Bayesian theorem which uses prior and posterior probabilities.

**bioinformatics-** The science of informatics as applied to biological research. Informatics is the management and analysis of data using advanced computing techniques.

**BLAST-** Basic Local Alignment Search Tool. An algorithm for performing similarity searches through local alignments.

**blood fluke-** A term used to refer to *Schistosoma*, a trematode flatworm.

**cDNA-** Complimentary DNA. Single-stranded DNA that has been synthesized from an mRNA template by reverse transcriptase.

**centromere-** The cinched "waist" of the chromosome essential for the division and the retention of the chromosome in the cell. Uniquely specialized region of the chromosome to which spindle fibers attach during cell division.

**cercariae** (plural, singular = cercaria)- the invasive larval stage of the blood fluke.

**CLUSTALW-** A general purpose program for performing multiple sequence alignments of DNA or protein sequences.

**contig-** Short for contiguous. Refers to a contiguous set of overlapping DNA sequences in the context of a sequencing project. Also referred to as an EST assembly, tentative consensus sequence, or gene cluster.

**definitive host-** The host in which the sexual reproduction of a parasite takes place

**erythrocytes-** Blood cells.

**escape glands-** schistosome cercarial glands that excrete their contents when the cercaria emerges from its snail host.

**EST-** Expressed Sequence Tag. Short, single-pass reads from mRNA that are usually produced in large numbers in the context of sequencing projects. Represent portion of DNA that is expressed.

**EST assemblies-** see "contig".

**ESTScan-** Program for detecting ORFs (open reading frames); able to find and correct sequence errors resulting in frame shifts within the coding sequence.

**e-value-** Expectation value. For a given score, (e.g. BLAST) the number of hits in a database search that are expected to be seen by chance. Takes into account the size of the database. The lower the E-value, the more significant the score.

**expectation maximization-** A technique for estimating hidden parameters. Used by MEME.

**fibrosis-** Formation of scar-like tissue.

**FISH-** Fluorescent In Situ Hybridization. A laboratory technique used to determine how many copies of a specific segment of DNA are present or absent in a cell in which a special region of a chromosome is stained with a dye that emits colored light when exposed to ultraviolet light.

**FrameFinder-** Program for detecting ORFs.

**gene clusters-** See “contig”.

**Gibbs sampling strategy-** Local multiple sequence alignment method that uses a stochastic algorithm.

**glycocalyx-** A sticky layer of a cell wall that consists of proteins and/or polysaccharides and functions to maintain osmotic pressure in the organism.

**Golgi apparatus-** Membrane-bound organelle in eukaryotic cells where the proteins and lipids made in the endoplasmic reticulum are modified and sorted.

**granuloma-** The formation of a nodule as a result of inflammation.

**head gland-** One of the glands of *Schistosoma mansoni*. Postulated to contain secretory bodies of proteins that function in the adjustment of the schistosomulae post-penetration.

**HMM-** Hidden Markov Model. A statistical model where the system being modeled is assumed to be a Markov process (a simple stochastic process in which the distribution of future states depends only on the present state and not on how it arrived in the present state) with unknown parameters, and the challenge is to determine the hidden parameters, from the observable parameters, based on this assumption. The extracted model

parameters can then be used to perform further analysis, for example for pattern recognition applications.

**homology**- Pertaining to phylogeny. Particular features (e.g. genes or proteins) in different individuals that are descended from the same feature in a common ancestor.

**immunogenic**- Possessing the ability to elicit an immune response.

**immunogenicity**- The ability of an antigen or vaccine to stimulate an immune response.

**information content**- Referring to the amount of information a particular motif found by MEME contains. Highly conserved positions in the motif have high information; positions where all letters are equally likely have low information.

**intermediate host**- Host that serves as a temporary but essential environment for the completion of a parasite's life cycle.

**InterPro**- A federated database of profiles, patterns, and HMMs for detecting protein domains.

**LC-MS/MS**- Liquid Chromatography/Mass Spectrometry/Mass Spectrometry. A technique that combines the solute separation power of HPLC, with the detection power of a mass spectrometer for identification of proteins.

**lumen**- The cavity or channel within a tube or tubular organ such as a blood vessel or the intestine.

**malaria**- An infective disease caused by a protozoan parasites that is transmitted through the bite of an infected *Anopheles* mosquito.

**MAST**- Motif Alignment Search Tool. A tool for searching sequence databases for motifs found by MEME.

**Matlab-** A commercial package (The MathWorks) which operates as an interactive programming environment, especially good for mathematical operations and working with matrices.

**MEME-** Multiple Expectation Maximization for Motif Elicitation. A tool for finding sequence motifs.

**metazoan-** Multicellular organism.

**miracidia** (plural, singular = miracidium)- the small free-swimming larvae of *S. mansoni* that hatch from eggs present in host feces, swim to find their freshwater snail intermediate host, and penetrate snails tissues where they develop into sporocysts.

**MS/MS-** Mass Spectrometry/Mass Spectrometry. Tandem mass spectrometry. A method by which peptide sequences are solved from the mass-to-charge ( $m/z$ ) fragmentation patterns of ions produced from collision-induced-dissociation.

**multiple sequence alignment-** A bioinformatics tool that compares multiple DNA or amino acid sequences and aligns them to highlight their similarities.

**oral sucker-** The part of the *S. mansoni* cercaria that works its way into its host's skin.

**ORESTES-** Open Reading frame Expressed Sequence Tags. A strategy for preferentially generating ESTs of the central, and thus most informative portion of the transcript. Also frequently identifies less abundant mRNAs.

**parasitophorous vacuolar membrane-** the membrane surrounding the vacuole that is created by plasmodia for survival within host erythrocyte cells.

**parasitophorous vacuole-** The vacuole that is created by plasmodia for survival within host erythrocyte cells.

**pathogenicity-** Capacity to cause disease.

**PEXEL motif**- Plasmodium Export Element. A five amino acid conserved sequence motif found in the malaria parasite, *P. falciparum*, that allows it to survive and multiply by exporting multiple remodeling and virulence proteins across the membrane of the parasitophorous vacuole into human erythrocytes.

**PfEMP1**- Plasmodium falciparum erythrocyte membrane protein 1. An important virulence protein in the malaria parasite.

**PSPM**- Position Specific Probability Matrix. Used by MEME to represent the observed frequency of each letter in any motif it finds. Columns correspond to letters in the alphabet, rows correspond to position in the motif.

**PSSM**- Position Specific Scoring Matrix. A log-odds matrix calculated by taking 100 times the log (base 2) of the ratio  $p/f$  at each position in the motif, where  $p$  is the probability of a particular letter at that position in the motif, and  $f$  is the background frequency of the letter. Used by MAST to detect occurrences of the motif in sequence databases. Columns correspond to letters in the alphabet, rows correspond to position in the motif.

**postacetabular glands**- Part of *S. mansoni*'s cercarial morphology. Three pairs of glands are located posterior to the acetabulum (ventral sucker). Vesicle secretions produced by these glands contain various enzymes, including proteases and high levels of calcium, making them important in skin penetration.

**preacetabular glands**- Part of *S. mansoni*'s cercarial morphology. Two pairs of glands located anterior to the acetabulum (ventral sucker). Produce mucus and help cercariae adhere to surfaces.

**PRINS**- Primed In Situ Hybridization. An alternative method to traditional *in situ* hybridization for the identification of chromosomes in metaphase spreads or interphase nuclei. Denatured DNA is hybridized to short DNA fragments, or designed oligonucleotides and then primer extension is carried out with the appropriate polymerase in the presence of labeled nucleotides.

**proteome-** The total complement of proteins expressed by an organism.

**proteomics-** The study of the proteome, employing methods that separate, quantify and identify proteins.

**protozoan-** Single-celled eukaryote.

**PFGE-** Pulsed Field Gel Electrophoresis. A gel electrophoretic method for the separation of megabase fragments of DNA based on continuous alteration of the angle at which the electrical field is applied.

**p-value-** The p-value indicates the probability that the result obtained in a statistical test is due to chance rather than a true relationship between measures. Small p-values indicate that it is very unlikely that the results were due to chance.

**reporter gene-** A gene whose gene product is easily detected (e.g. through the use of fluorescent labeling).

**RT-PCR-** Reverse Transcriptase Polymerase Chain Reaction. Method for amplifying DNA or RNA segments using heat-resistant enzymes. First, complementary DNA (cDNA) is made from an RNA template, using a reverse transcriptase enzyme, and then some of it is used in a PCR reaction to produce large quantities.

**schistosome:** The blood fluke or flatworm.

**schistosomiasis-** The disease caused by species of *Schistosoma*.

**schistosomula** (plural, singular = schistosomules)- One of the life cycle stages of *Schistosoma*. Cercaria are transformed into schistosomula after they penetrate the skin.

**secretome-** The set of soluble proteins secreted into the extracellular environment of a cell.

**secretory vesicles-** Membrane bound structure derived from the Golgi apparatus, containing material to be released from the cell.

**signal peptide-** A short peptide sequence (15-60 amino acids long) that directs the post translational transport of a protein. Some signal peptides are cleaved from the protein by signal peptidase after the proteins are transported. Signal peptides may also be called targeting signals or signal sequences.

**signal sequence trap method-** A method for selecting cDNAs encoding secreted and surface proteins with N-terminal signal peptides. cDNAs are fused with a signal sequence-deficient reporter gene with the expectation that those cDNAs containing a signal sequence will result in surface expression of the protein produced.

**SignalP-** A program for predicting the presence of signal peptides and location of signal peptide cleavage sites in amino acid sequences from different organisms, based on pattern recognition of known motifs for signal peptidase I found in higher eukaryotes.

**singletons-** ESTs that are not contained in an assembly.

**sporocysts-** One of the life cycle stages of *Schistosoma*. Miracidia transform into sporocysts after they penetrate the tissues of their intermediate host (the snail). Sporocysts then multiply asexually to produce hundreds of thousands of cercariae.

**tegument-** The outer membrane of the blood fluke. The tegument in *Schistosoma* is uniquely 3-layered.

**tentative consensus sequences-** See “contig”.

**Th1-type response-** Two types of T-helper cells boost the immune attack. Th1-type cells stimulate macrophages and natural killer cells, which directly attack microbes that replicate in the body’s cells. This type of response is called cellular immunity.

**Th2-type response-** Two types of T-helper cells boost the immune attack. Th2 cells attack foreign matter too large to be killed by macrophages or natural killer cells, by preferentially stimulating B cells to produce antibodies. This type of response is called humoral immunity.

**UNDP-** United Nations Development Program.

**unsupervised learning-** A method of machine learning where a model is fit to observations. Does not involve any prior knowledge, unlike supervised learning. A data set of input objects is gathered and treated as a set of random variables, for which a joint density model is then built.

**VTs-** Vacuolar Transport Sequence. An eleven amino acid conserved sequence motif found in the malaria parasite, *P. falciparum*, that allows it to survive and multiply by exporting multiple remodeling and virulence proteins across the membrane of the parasitophorous vacuole into human erythrocytes. (The PEXEL motif is contained within the VTs.)

**ventral sucker-** See “acetabulum”.

**weight matrix-** A flexible type of quantitative motif descriptor that contains weights or scores for each amino acid in every position.

**Weka-** Data mining software written in Java. Collection of machine learning algorithms for data mining tasks.

**WHO TDR-** World Health Organization Special Program for Research and Training in Tropical Diseases.

**whole genome shotgun sequencing-** A method of sequence where all the DNA is first broken into fragments and the fragments are then sequenced at random and assembled together by looking for overlaps.

## I. INTRODUCTION

### A. Introduction of Subject

*Schistosoma mansoni* is a parasitic flatworm that causes the disease schistosomiasis and infects an estimated 200 million people worldwide. Schistosomiasis is generally considered to rank second behind malaria among parasitic/infectious diseases in global importance. It is endemic to 76 countries, mostly underdeveloped, and is usually associated with water resource development projects that expand the habitat of the parasite's intermediate host, the freshwater snail (Johnston, Blaxter *et al.* 1999). There is medical interest in characterizing the parasitic proteins that interact with the human host for either the development of vaccines or identification of drug targets. The proteins that the larval stage of the parasite secretes extracellularly just prior to infection of the definitive human host have been recently isolated and identified (Knudsen, Medzihradsky *et al.* 2005). Proteins contained in the adult tegument, the metabolically active outer surface of the parasite, have also recently been isolated and identified (van Balkom, van Gestel *et al.* 2005). The recent discovery of highly conserved sequence motifs in proteins exported by the protozoan parasite *Plasmodium falciparum*, which causes malaria, were the motivation of this research (Hiller, Bhattacharjee *et al.* 2004). We hypothesize that a conserved motif in proteins that are either secreted extracellularly or anchored into the tegument underlies a common export mechanism. The goals of this project are to elucidate a conserved sequence motif across *S. mansoni* secreted proteins and to functionally annotate the proteins to hypothesize about the underlying mechanism of secretion used by the invading parasite.

### B. Importance of Subject

According to the World Health Organization's Tropical Disease Research Unit (WHO TDR), approximately 600 million people worldwide are at risk for schistosomiasis infection, 200 million people are currently infected, 20 million severely. The majority of infections occur in under-developed countries (TDR 2002). Reported mortality estimates

range from 11,000 per year (TDR 2002) to 500,000 per year (Johnston, Blaxter *et al.* 1999). It has been given a Category 2 rating by the World Health Organization, meaning that a control strategy exists but has not resulted in a persistent reduction in the disease burden (TDR 2002). Reinfection is common and can lead to liver, intestine, and urinary tract damage and can stunt growth and cognitive development (Remme, Blas *et al.* 2002). The parasite also infects approximately 165 million head of livestock (Chitsulo, Engels *et al.* 2000).

### **C. Knowledge Gap**

Two drugs introduced in the 1970s are still the only ones commercially available for the treatment of schistosomiasis: praziquantel and oxamniquine (Cioli and Pica-Mattoccia 2005). Oxamniquine is only effective against *S. mansoni*, limiting its use to South America where *S. mansoni* is the only species present. Praziquantel is a broader spectrum drug that has been used in other parts of the world. Market competition has driven down the price of praziquantel, but not oxamniquine, due to its geographical limitations. This has resulted in countries even in South America decreasing their use of oxamniquine in favor of praziquantel. This has effectively made praziquantel the only drug currently available against the disease (Cioli and Pica-Mattoccia 2005). Praziquantel is effective in a single dose, but given that infections occur mainly in under-developed countries (85% in sub-Saharan Africa) and that reinfection is common, the cost of \$0.40 per treatment is prohibitive (Cioli and Pica-Mattoccia 2005). Massive funding from the Gates Foundation is allowing implementation of a program called the “Schistosomiasis Control Initiative”, which will provide praziquantel treatments to a few select African nations, frequently to school-aged children (Cioli and Pica-Mattoccia 2005). But full-blown resistance to praziquantel could occur at any time (Chitsulo 2005), so a schistosomiasis vaccine, as well as new lead chemotherapeutics, need to be pursued.

Both drugs are chemotherapeutics whose modes of action are not completely understood. Both drugs result in selective toxicity to the adult worm. Their structures are shown in Figure 1 below. It is known that oxamniquine’s mode of action is dependent upon the presence of the hydroxymethyl group (Cioli and Pica-Mattoccia 2005). Some interesting

features of oxamniquine activity include: 1) schistosomes have a delayed reaction to it (5-7 days after a 30 minute in vitro exposure), 2) the length of exposure can be as short as 15 minutes for the drug to be effective, 3) it is more effective against male worms than female worms, and 4) it has little activity against immature schistosomes (Cioli and Pica-Mattoccia 2005). Resistance to oxamniquine has been proven both in the laboratory (Rogers and Bueding 1971) and in the field (Katz, Dias et al. 1973) and it has shown to be complete (Pica-Mattoccia, Dias et al. 1993). This resistance does not, however, spread throughout the population, as cases of it have been confined and random (Cioli and Pica-Mattoccia 2005). It has been proven that resistance to the drug is a recessive trait (Cioli, Pica-Mattoccia et al. 1992), which has led to the suggestion that resistant schistosome are missing some function that activates the drug (Cioli and Pica-Mattoccia 2005). This missing function has been proven to be the enzyme sulfotransferase (Cioli and Pica-Mattoccia 2005). It has been shown that a particular sulfotransferase is specific to *S. mansoni*, and is necessary to confer sensitivity to the drug oxamniquine. Sulfotransferases function by transferring a sulfate group from a donor molecule (phosphoadenosine-phosphosulfate, PAPS) to the hydroxyl group of an acceptor substrate, oxamniquine, in this case. This creates an unstable sulfate ester which spontaneously dissociates, leading to an electrophile (positively charged molecule) capable of alkylating (forming covalent bonds with) other molecules, such as, in this case, schistosome DNA and other macromolecules. The sulfotransferase gene has not yet been cloned in *S. mansoni*. Schistosomes without a functional sulfotransferase have a lower fitness, as indicated by various measure of the vitality of their life cycle. This decreased fitness, in addition to the fact that the gene is recessive, is proposed as an explanation for why oxamniquine resistance does not spread throughout a population (Cioli and Pica-Mattoccia 2005).

Figure 1. Praziquantel (left) and Oxamniquine (right)

Praziquantel is effective not just against all species of schistosomes, but also against other trematodes and human and veterinary cestodes. The effectiveness of the drug is significantly reduced in animals that are immune-compromised (Sabah, Fletcher et al. 1985), though this has not yet been evidenced in humans (Karanja, Boyer et al. 1998). The drug has little effect on immature schistosomes (Gonnert and Andrews 1977), and the height of effectiveness against mature schistosomes is reached at two points: very early, -1 to +1 days from infection, and relatively late, 7 weeks post infection. The biggest effect of the drug is a huge increase in the amount of intracellular calcium in the parasite (Pax, Bettett et al. 1978) if calcium is present in the medium. The cause of this influx is not known, but it has been shown not be caused by alteration of either ATPases that pump calcium out of cells (Nechay, Hillman et al. 1980) or voltage-gated calcium channels (Fetterer, Pax et al. 1980). This huge increase in calcium causes severe paralysis of the parasite's musculature, causing the schistosome suckers to release their hold on the inner wall of blood vessels and the schistosome to migrate to the liver. Another significant effect caused by praziquantel is massive alterations of the parasite's tegument, also dependent on the presence of calcium. This increases the number of schistosome antigens present at the parasite surface, some of which have been identified and characterized (Doenhoff, Sabah et al. 1987) (Sauma and Strand 1990), which exposes antigens to the host immune response.

A pyrazio-isoquinoline ring system containing an asymmetric carbon atom that leads to two enantiomers referred to as *dextro*- and *laevo*- praziquantel form the base of

praziquantel structure. Despite the fact that the *dextro*- form is almost inactive while the *laevo*- form possesses most of the anti-schistosomal activity, most commercial preparations are a 50:50 mixture because isolating the *laevo*- form is an expensive process. Hypotheses regarding the mode of action include that praziquantel interacts with membrane phospholipids to change the permeability of the lipid bilayer (Harder, Goossens et al. 1988) (Schepers, Brasseur et al. 1988), and that it interacts somehow with glutathione S-transferase (GST) based on the presence of a pocket in the three-dimensional structure of GST that could fit praziquantel (McTigue, Williams et al. 1995). These hypotheses have been disproven, however. More recently it has been hypothesized that beta subunits of calcium-binding proteins are involved in praziquantel activity, based on them containing subsequences that are unique to schistosomes (Kohn, Anderson et al. 2001).

There is currently no vaccine available for schistosomiasis. Challenges involved in studying schistosomes include: 1) the lack of an animal model that adequately reflects the human response, 2) maintaining the life cycle of *Schistosoma* in the laboratory (*S. mansoni* is used most often because it is the easiest to maintain in the laboratory), 3) finding a vaccine with broad spectrum activity against all five species of *Schistosoma* that infect human (or at least the three main species), and 4) the fact that the parasite goes through three life cycle changes within its human host means that the antigens presented to the host are always changing. There is reason to believe that a vaccine can be developed, however, as there is ample evidence that humans acquire some level of resistance after recurrent schistosome infection (Bergquist 1998). In the mid-90s the WHO selected six promising anti-larval or anti-worm vaccine candidate antigens for testing in mouse and rat including: glutathione-S-transferase (Sm28) and the muscle protein paramyosin (Sm97), both found in the schistosomula and adult stages; triose phosphate isomerase (TPI), a membrane antigen (Sm23), and myosin heavy chain (rIrV5), all found in all stages; and the antigenic membrane protein fatty acid-binding protein (Sm14), found only in the schistosomula stage (Mountford and Jenkins 2005). The target of consistently inducing 40% protection was not reached, however, most likely due to instability of formulations (Bergquist 1998). The ability to scale up production according to GMP standards has turned out to be an important criterion in assessing vaccine candidates (Bergquist 2004).

New candidate antigens are needed and “expectations of finding additional candidates through mining the expanding genomics databases and through proteomics analysis are justifiable” (Bergquist 2004). The underlying mechanisms of human resistance to schistosomiasis and the immune responses elicited by the various life cycle stages or particular antigens are not well understood. For example, some antigens have been shown to require a Th2-type response, others a Th1-type response (Bergquist 2004). There is also disagreement in the research community about the desired type of immune response that a vaccine should achieve. This lack of agreement and understanding has lead to different adjuvants being selected for delivery of antigens and the selected adjuvant itself has an effect on the immune responses elicited (Mountford and Jenkins 2005). Control strategies now seem to be aiming towards development of vaccines that provide partial protection that can be complemented with chemotherapeutic drugs (Bergquist 2004).

## **II. BACKGROUND**

### **A. Related Research**

*S. mansoni*

The Schistosoma Genome Network (SGN) is one of the Parasite Genome Initiatives of the WHO. It is an international collaboration of laboratories that has received support from the WHO/UNDP/World Bank Special Program for Research and Training in Tropical Diseases (TDR) since 1994 (Johnston, Blaxter et al. 1999). The financial support for this project provided by WHO is motivated by the desire to:

- “1) increase knowledge of parasite molecular biology, especially with respect to mechanisms of drug resistance, antigenic variation, and genetic diversity;
- 2) identify genes with key cellular functions that could represent new drug targets and to identify antigens with diagnostic and/or vaccine potential;
- 3) where practical, develop a physical map of the parasite’s genome and/or other library resources for distribution to the wider research community; and
- 4) curate, analyze, and disseminate parasite genome data” (Johnston, Blaxter et al. 1999).

The first *S. mansoni* genes were cloned in the early 1980s, but by the early 1990s there was still little progress made towards elucidating the *S. mansoni* genome: only a few more than one hundred cDNAs had been deposited in GenBank (Ohler and Niemann 2001). Initial efforts of the SGN focused on generating large numbers of expressed sequence tags (ESTs). In 1994 partial sequencing of *S. mansoni* cDNA clones generated 607 ESTs, of which 16% had been previously identified, 22% showed homology to other organisms, and 33% showed no significant homology to other organisms (Ohler and Niemann 2001). This was one of the first large-scale studies to illuminate new *S. mansoni* genes.

A large-scale effort across multiple labs in the State of São Paulo was initiated in 2001 to sequence *S. mansoni* EST clones generated by the ORESTES low-stringency RT-PCR amplification technique (Williams and Pierce 2005). The central portion of messages containing the more conserved, function-defining coding regions are amplified in this technique through the use of arbitrary primers and low-stringency RT-PCR (Fietto, DeMarco et al. 2002). 163,000 ESTs from six developmental stages of *S. mansoni* were sequenced, resulting in 31,000 gene clusters, covering an estimated 92% of an estimated 14,000 expressed genes (Verjovski-Almeida, DeMarco et al. 2003). Approximately 124,000 ESTs, 11,000 contigs, and 15,000 singletons resulting from this effort are available to the public through the *S. mansoni* Assembled ESTs database (April 2002, URL:<http://cancer.lbi.ic.unicamp.br/schisto6/>).

Additional EST sequencing efforts have resulted in significant progress towards identifying both *S. mansoni* and *S. japonicum* genes. *S. mansoni* EST sequences have been assembled, archived and made available to the public at The Institute for Genomic Research's (TIGR) *S. mansoni* Gene Index (SMGI) database (The TIGR Gene Index Databases, The Institute for Genomic Research, Rockville, MD 20850, URL: <http://www.tigr.org/tdb/tgi>, (Quackenbush, Liang et al. 2000) . It contains approximately 138,000 ESTs, 13,000 tentative consensus sequences, and 21,000 singletons (version 5, January 22, 2005).

In June 2003, the Sanger Institute initiated a 5x whole genome shotgun sequencing effort and clusters were created using a combined set of Sanger and TIGR sequences, giving a

total of 8x coverage of the genome (El-Sayed, Bartholomeu et al. 2004). Sanger's *S. mansoni* GeneDB (version 3.0, October 14, 2005) contains a total of 50,376 contigs. A project to complete sequencing of a 1.1 Mb *S. mansoni* BAC contig has also been initiated at The Sanger Institute.

The SGN's focus has been on *S. mansoni* mainly. This is evident in the comparative numbers of ESTs contained in NCBI's EST database, dbEST. As of June 12, 2006, it database contains 158,841 *S. mansoni*, 97,526 *S. japonicum*, and 6 *S. haematobium* ESTs (URL: <http://www.ncbi.nlm.nih.gov/dbEST/index.html>). There is, however, growing understanding that the different schistosome species vary in many ways including their range of definitive hosts, egg production, pathogenicity, and immunogenicity (Le, Blair et al. 2002). This has motivated various projects that focus on other species including the sequencing of 43,000 ESTs from the egg and adult stages of *S. japonicum* as part of a cooperative project between the Chinese National Human Genome Center at Shanghai (CHGCS), Shanghai Institute of Parasitology, Chinese Academy of Medical Science, and Shanghai Second Medical University. 13,000 gene clusters resulted, of which 35% had no homology to known genes and 75% had not been previously reported (Hu, Yan et al. 2003). All ESTs, cDNAs, and EST assemblies are available through the Chinese Human Genome Center at Shanghai (URL: <http://schistosoma.chgc.sh.cn/sj-old/index.htm>) and have also been deposited in GenBank. The availability of this data set is a great asset in the study of *S. mansoni*, as the two organisms are closely related.

Very little work has been done to date on *S. haematobium*. But recently a collaboration has begun at The Sanger Institute to generate 15,000 ESTs from both *S. haematobium* and *Fasciola hepatica*. *F. hepatica* will be useful in comparative studies because it is also a platyhelminth digean that is phylogenetically close to *Schistosoma* and is an important human and veterinary pathogen. This EST data will be available at Sanger's Sm GeneDB (<http://www.genedb.org/>).

The signal sequence trap method was first developed and described in the early 1990s as a method for selecting cDNAs encoding secreted and surface proteins with N-terminal signal

peptides. cDNAs are fused with a signal sequence-deficient reporter gene with the expectation that those cDNAs containing a signal sequence will result in surface expression or secretion of the protein produced. It is an especially effective technique for studying genomes of organisms not yet sequenced. The first application of this technique for identifying surface and secreted proteins from any pathogenic organism was performed in *S. mansoni*, where a protein kinase, tetraspanins similar to human cell surface antigens, and previously characterized *S. mansoni* surface proteins were identified from the adult stage blood fluke (Smyth, McManus et al. 2003). Further work applying this method to cDNAs expressed during various *S. mansoni* life cycle stages revealed additional cDNAs containing a signal sequence as well as one encoding a seven transmembrane receptor (Pearson, McManus et al. 2005). A bioinformatics analysis of 100 signal peptides each from 4 different species including *Schistosoma*, human, *Escherichia coli*, and *Nippostrongylus brasiliensis* (a parasitic nematode) was also performed. It was found that the sequence composition of signal peptides varies across the four species, especially in residues flanking the cleavage site. Another interesting result from this study was that cDNAs encoding *S. mansoni* elastases that were fused to a reporter gene did not result in surface expression, despite the fact that elastases are known to be secreted by the invasive larval stage of schistosomes (Pearson, McManus et al. 2005). It was suggested that this was either due to the transfected COS7 cells used in this method being able to recognize some, but not all, signal sequences employed by *S. mansoni*, or other incompatibilities in protein trafficking in different species that cause incorrect reporter processing. **The implication is that traditional signal peptides used for secretion of proteins by other eukaryotes may not be employed by the invasive larvae of schistosomes** (for traditional signal peptides, see Current Understanding- Protein Secretion and Signal Peptides, page 35).

The accumulation of large amounts of genomic data for *S. mansoni* has enabled recent studies of its proteome, the complete set of proteins expressed by the organism. A study of *S. mansoni* cercarial secretions, which employed 1D gel electrophoresis combined with LC-MS/MS, identified a total of 172 proteins from skin lipid-induced, mechanically induced, and uninduced samples (Knudsen, Medzihradszky et al. 2005). A study of the *S.*

*mansoni* adult tegumental sub-proteome, which also involved the use of 1D and 2D gel electrophoresis combined with LC-MS/MS and MALDI TOF-TOF, identified 740 proteins, 43 of which were found to be unique to the tegument (van Balkom, van Gestel *et al.* 2005). The first proteomic analysis of soluble proteins from four different life cycle stages of *S. mansoni* was performed using 2D gel electrophoresis and resulted in the identification of 32 proteins by MS/MS protein sequencing (Curwen, Ashton *et al.* 2004).

cDNA microarrays have been used to identify *S. mansoni* gender-associated genes (Hoffmann, Johnston *et al.* 2002). The first oligonucleotide microarray applied to studying *S. mansoni* was also used for studying gender-associated genes and was comprised of approximately 50% of the adult parasite's transcriptome (Fitzpatrick, Johnston *et al.* 2005). 197 transcripts were shown to have a "gender-biased pattern of gene expression" in adult schistosomes.

### *Plasmodium falciparum*

*P. falciparum* is a protozoan (unicellular) parasite that causes malaria. Plasmodia live within the host's erythrocytes surrounded by a lipid membrane, termed the parasitophorous vacuolar membrane (Lingelbach and Joiner 1998). An ER-type signal sequence (see Background- Protein Secretion and Signal Peptides) is responsible for parasitic proteins being exported across the parasitic plasma membrane and into the lumen of the parasitophorous vacuole (Wickham 2001). It has been found that additional signaling sequences are necessary for proteins to be transported across the parasitophorous vacuole into the erythrocyte cytoplasm.

Through the use of fluorescence microscopy, two different *P. falciparum* histidine-rich proteins (histidine-rich protein I, PfHRPI, and histidine-rich protein II, PfHRPII) were found to contain a domain, immediately after the signal sequence and before a histidine-rich region, that is necessary for export of green fluorescent protein (GFP) from the lumen of the parasitophorous vacuole to the erythrocyte cytoplasm (Lopez-Estraño, Bhattacharjee *et al.* 2003). For PfHRPI this domain was SNNCNNGNGSGDSFDFRNKRTLAQKQ and for PfHRPII this was FNNNLCSKNAKGLNLNKRLLYETQAHVDD. In both cases the

domain was within 40 amino acids of the signal sequence and needed to be exposed at the N-terminus in order for export to the cytoplasm to occur.

Through N-terminal sequence alignment a conserved pentameric sequence motif, RxLxE, referred to as the Pexel motif (*Plasmodium* export element), was also found at the N-terminus of other exported proteins (Marti, Good *et al.* 2004). The Pexel motif occurs in about 160 soluble and insoluble cytoplasmic-side proteins within 60 amino acids of an upstream signal sequence, and in about 225 virulence proteins, some of which lack the signal sequence. The motif was verified by fusing fluorescent signaling proteins to proteins where this pentameric motif had been either removed or mutated and demonstrating that this did not result in fluorescence being exported to the cytoplasm. An eleven amino acid motif, RxSRILAExxx (RILAE forms the core), referred to as a vacuolar transport sequence (VTS), that has features in common with the Pexel motif and also occurs 60 amino acids downstream of a signal sequence, was found in about 320 proteins through the reiterative use of MEME and MAST (Hiller, Bhattacharjee *et al.* 2004). It was experimentally proven to be responsible for both soluble and insoluble proteins being exported from the parasitophorous vacuole to the erythrocyte cytoplasm. It has recently been suggested that the region necessary for export in *P. falciparum* is actually larger (~30 aa) than the Pexel motif, but that Pexel is the core of the region and contains the most conserved amino acids (Bhattacharjee, Hiller *et al.* 2006). Most interestingly, it has also been found that in hundreds of secretory proteins in a divergent eukaryote, *Phytophthora*, there is conservation of the RxLR motif (Bhattacharjee, Hiller *et al.* 2006). *Phytophthora* is an oomycete that is the causative agent of potato late blight. Three different species have been shown to contain the RxLR motif in a position that is conserved across *Plasmodium* and *Phytophthora*. It was also found that there is conservation of E/D residues with 25 amino acids downstream of the RxLR motif in *Phytophthora* species. It is important to note that predictive algorithms used to find the plasmodial motif did not recognize the RxLR motif in *Phytophthora*. Rather this motif was experimentally proven to have equivalent function in the two species by expressing a chimera of GFP and a 50 amino acid sequence from the *Phytophthora* avirulence protein AVR3a containing the RxLR motif in *P. falciparum*. The result was expression of GFP in the cytoplasm of *P. falciparum*.

A comparison of the VTS and Pexel motifs and the methodologies used to discover them found that the pentameric Pexel motif is contained within the 11 amino acid VTS motif, but that there is a 30% difference in their corresponding sets of secreted proteins (Haldar, Hiller *et al.* 2005). It is postulated that the differences in the motifs are a result of the two different methodologies used: the VTS motif was found using the MEME position-specific probability matrix, while the Pexel motif was found through sequence alignment and using a linear two exon-structured pattern to search databases of predicted proteins. There is a *P. falciparum* protein known to be exported that does *not* contain the two exon structure. Two different secretion models are proposed (Haldar, Hiller *et al.* 2005). In the first model, proteins are secreted from the lumen of the parasitophorous vacuole to the lumen of specialized sorting and trafficking organelles, similar to the Golgi called Maurer's clefts, via vesicles and then into the erythrocyte cytosol or plasma membrane. In the second model, proteins are delivered across the plasma membrane of the parasitophorous vacuole into the erythrocyte cytoplasm, where they associate with the cytoplasmic side of the Maurer's clefts.

Through N-terminal alignment of 60 PfEMP1 proteins it was found that the virulence protein encodes a motif, linearized to SAKHLLDRIGKDVHDQVK, that is different from the motif (Pexel) found in other virulence proteins, but that shares features with it (Marti, Good *et al.* 2004). Hiller *et al.* discovered a different motif in PfEMP1 proteins, QFFRWFSEWSE, through reiterative use of MEME and MAST using an earlier discovered motif (VTS) (Hiller, Bhattacharjee *et al.* 2004).

## **B. Current Understanding**

### *S. mansoni*

There are 5 species of *Schistosoma* that infect humans: 4 intestinal schistosomes including *S. intercalatum*, *S. japonicum*, *S. mekongi*, *S. mansoni*, and 1 urinary schistosome named *S. haematobium*. Each species has a specific freshwater snail as its intermediate host. 85% of schistosomiasis cases occur in sub-Saharan Africa. *S. haematobium* is the most prevalent and widespread species in Africa and the Middle East. *S. intercalatum* occurs in 10 countries in the rainforest belt of Africa. *S. japonicum* is restricted to the Pacific region

including China and the Philippines. *S. mekongi* is found in limited areas of Laos and Cambodia. *S. mansoni* is found in Africa and is the only species seen in South America including Brazil, Venezuela, and Surinam.

The life cycle of *S. mansoni* consists of 6 stages (Figure 2). Parasitic eggs contained in human feces hatch into a larva, referred to as miracidia, upon contact with fresh water. The miracidia penetrate the tissue of their snail intermediate host, *Biomphalaria glabrata*, in which they develop into sporocysts. Sporocysts multiply asexually, producing hundreds of thousands of cercariae. The cercariae are free swimming and are induced by human skin lipid to lose their tails and penetrate human skin, at which time they are transformed into schistosomula. Schistosomula use their host's circulatory system to migrate to the blood vessels of the liver, intestine, or bladder. They then sexually mature into adult schistosomes, form pairs, and live in copula for the rest of their lives, laying 300 eggs per day.

Schistosomiasis is caused by an immune response to eggs that are lodged in tissues, failing to be excreted (Capron and Capron 1994). Granulomas form in response to the eggs and result in fibrosis that can cause enlargement of the liver, urinary obstruction in the bladder, and kidney damage. Clinical signs do not appear until the worm burden increases through repeated infection causing an increase in the number of granulomas. Symptoms can include abdominal pain, cough, diarrhea, extremely high white blood cell count, fever, fatigue, and enlarged liver and spleen. People repeatedly infected can have liver, intestine, lung, and bladder damage.

The *S. mansoni* is a diploid organism with seven pairs of somatic chromosomes and one pair of sex chromosomes and a genome that is approximately 270 Mbp (Simpson, Sher *et al.* 1982), about one tenth the size of the human genome. It is at least 30% repetitive (Le Paslier, Pierce *et al.* 2000), may be as much as 60% repetitive (Johnston, Blaxter *et al.* 1999), and has a GC content of 34% (Hillyer 1974). Recent findings suggest that much of this repetitive composition is comprised of mobile genetic elements, or retrotransposons, which have likely played a large role in their evolution (Brindley and Yoshino 2003). The number of expressed genes is estimated to be 15-20,000.

## Schistosomiasis

Figure 2. Life cycle of schistosomes

The chromosomes of *S. mansoni* condense during cell division, making it possible to view them via light microscopy (Johnston, Blaxter *et al.* 1999). They are large with varying sizes, shapes, centromere positions, and banding patterns. Individual chromosomes cannot be isolated because even the smallest chromosome is too large to be separated using pulsed field gel electrophoresis (PFGE) (Johnston, Blaxter *et al.* 1999), but chromosome maps can be generated through such techniques as fluorescent in situ hybridization (FISH) and primed in situ hybridization (PRINS) techniques (Short, Liberatos *et al.* 1989).

Two of the three sample sets used in this study involve proteins released from the *S. mansoni* cercarial stage just before it penetrates the skin and infects its human host. The ventral sucker (acetabulum) plays an active role in skin exploration and penetration. During skin exploration it deposits mucus and attaches to these deposits alternately with the oral sucker. It serves to anchor the parasite to the skin while the oral sucker works its way through layers of skin (Stirewalt and Kruidenier 1961).

Figure 3. Scanning electron micrograph of a *S. mansoni* cercariae  
 (a) oral sucker, (b) mouth, (c) acetabulum/ventral sucker,  
 (d) body/tail junction, (e) tail and (f) tail bifurcation.  
 Spines are easily visible covering both the body segment and tail.  
 The entire length of the organism is approximately 500  $\mu\text{m}$ ,  
 but can vary considerably due to its ability to contract and elongate.

 and the publishers of Micron. (Dorsey, Cousin et al. 2002).

Schistosome cercaria are reported to have no fewer than four different types of glands including 1) the escape glands, 2) the head gland, and 3) two sets of acetabular glands- pre and post (Schmidt and Roberts 2000). The escape glands have been shown to expel their contents when cercaria emerge from their snail host (Schmidt and Roberts 2000). The head gland has narrow duct openings into the tegument in cercariae that have recently emerged from their snail hosts. In contrast, in new schistosomules the head

gland has greatly expanded ducts which are filled with secretory bodies (Dorsey, Cousin et al. 2002), which likely function in the adjustment of the schistosomulae post-penetration. The acetabular glands are named according to their position relative to the acetabulum (ventral sucker). Two pairs of preacetabular glands are located anterior to the acetabulum and three pairs of postacetabular glands are located posterior to the acetabulum. The preacetabular glands produce mucus and help cercariae adhere to surfaces, while the postacetabular gland vesicle secretions contain various enzymes, including proteases, as well as high levels of calcium, making them important in skin penetration. It has been shown that an influx of calcium is necessary but not sufficient for release of proteinases from cercarial preacetabular glands (Fusco, Salafsky et al. 1991). Figures 4 and 5 provide two different perspectives of the head and acetabular glands.

*Schistosomes* are eukaryotic organisms of the Kingdom Metazoa, Phylum Platyhelminthes, Class Trematoda, Subclass Diegenea, Order Strigeidida, Family Schistosomatidae, and Genus *Schistosoma*. They are often referred to as blood flukes. They are a unique family among the Digeneans, along with two other families, Spirorchiidae and Sanguinicolidae, in that they have two host life cycles, a snail intermediate host and a vertebrate (human) definitive host; most Digeneans have three host life cycles including a metacercariae stage (Loker and Mkoji 2005). The tegument of all three of these families is also unique in that it is bound by a double lipid bilayer, whereas other flukes have only a single lipid bilayer (McLaren and Hockley 1977). This additional lipid bilayer is most likely needed because the adult schistosome lives in the vascular system of its definitive human host.

Figure 6. Components of the *S. mansoni* tegument  
Reprinted with permission from Dr. Malcolm Jones  
(Jones, Gobert et al. 2004).

The morphology of the tegument and its involvement in host-parasite interactions has been extensively studied. The tegument undergoes changes as the schistosome passes through the different stages of its life cycle. Miracidia possess a tegument consisting of a layer of ciliated sheets, which is shed just before they infect their snail intermediate host. Cercaria possess a tegument that has an osmotic-protective, but highly immunogenic glycocalyx layer. This is shed within a few hours of penetrating the human host and is replaced by an immune-evasive adult tegument (Jones, Gobert et al. 2004). Most characteristics of the tegument remain consistent throughout the different life cycles.

Proteins contained in postacetabular secretions (sample sets 1 and 2) are important to study because they are directly involved in initial human infection; they contain enzymes involved in breaking down skin components that allow the parasite to find its way into the bloodstream. Proteins contained in the tegument (sample set 3) are also important to study because the tegument serves as the major interface between the schistosome and its environment. Proteins isolated from postacetabular vesicles or the tegument are likely to contain antigenic proteins that could be good targets for drug or vaccine development.

### *Protein Secretion, Signal Peptides, and Propeptides*

Proteins often start out as inactive pre-pro-peptide precursors. The pre-domain consists of a signal peptide which directs the protein to the appropriate cellular compartment during synthesis and gets cleaved during this translocation process, while the pro-domain can have various functions once it is cleaved such as protein localization, regulation of activity, and involvement in protein folding. In secreted proteins the pre-domain is the signal that causes transport into the endoplasmic reticulum (ER) and, subsequently, the trans Golgi network (TGN), and the pro-domain is the signal that causes the proteins to be directed into the regulated secretory pathway for eventual export out of the cell (Alberts, Bray et al. 1994).

Signal peptides that direct proteins to the lumen of the ER are referred to as ER-type signal peptides. Signal peptides consist of a positively charged N-terminal region, a hydrophobic central segment, and a polar, but neutral, C-terminal region. Their structure is said to follow the (-3, -1) rule which states that in order for cleavage to occur correctly, small and neutral amino acids must exist at positions -3 and -1 relative to the cleavage site (Von Heijne 1983). ER-type signal peptides are cleaved by signal peptidase I. N-terminal anchor sequences are also capable of delivering peptides to the ER, of which there are several types. If only a signal peptide is present, the ribosome synthesizing the protein is signaled to deliver it to the lumen of the ER (High, Flint et al. 1991), while if either both a signal peptide and a signal anchor sequence is present or a signal anchor sequence alone is present, the protein is anchored into the ER membrane instead (Wahlberg and Spiess 1997).

All eukaryotic cells have an endoplasmic reticulum (ER), which plays a central role in lipid and protein biosynthesis. The membrane of the ER is the site of synthesis of the transmembrane proteins for most of the cell's organelles and all proteins that will be secreted outside the cell are initially delivered to the lumen of the ER. The ER is made up of a convoluted, interconnected set of tubules and sacs that extend throughout the cytosol and make up a continuous space called the ER lumen.

Once in the lumen of the ER, proteins are glycosylated, molecular chaperones aid protein folding, and misfolded proteins are identified and retrotranslocated to the cytosol, where they are degraded by a proteasome. Properly-folded proteins enter the Golgi apparatus, where the glycosylation of the proteins is modified and further posttranslational modifications, including cleavage and functionalization, may occur. They are then translocated to the cell surface via transport vesicles, in which further protein modification may occur. This is referred to as the constitutive secretory pathway and it operates in all cells. All eukaryotic cells require this type of secretion where proteins and small molecules leave the trans Golgi network in a steady stream in transport vesicles. These vesicles fuse with the plasma membrane causing their soluble contents to be released to the extracellular space, while the insoluble components provide new components for the cell's plasma membrane as they become incorporated into it.

Some of the proteins contained in the ER may contain a signal, or pro-domain, that causes them to either be retained in the ER or shuttled off into special secretory vesicles. Secretion via secretory vesicles is referred to as the *regulated* secretory pathway. It operates only in specialized secretory cells and is used to secrete soluble proteins and other substances such as hormones and enzymes rapidly and on demand. Similarly to transport vesicles, secretory vesicles fuse with the plasma membrane causing their soluble contents to be released to the extracellular space, but not until an extracellular signal is received (Alberts, Bray et al. 1994). Proteins destined for secretory vesicles accumulate in the trans Golgi network (TGN). The mechanism behind subsequent uptake into secretory vesicles is not fully understood, but is thought to resemble phagocytosis. When secretory vesicles bud from the TGN, their contents become greatly condensed.

As in the non-regulated secretory pathway, many of the proteins contained in secretory vesicles and destined to be exported are thought to undergo one or more rounds of cleavage, either while still in the TGN, in the secretory vesicles, or in the extracellular fluid after secretion has occurred.

Pro-domains become exposed at their N-terminal once the signal peptide is cleaved. Pro-domains are often cleaved immediately C-terminally of motifs containing multiple basic residues (Duckert, Brunak et al. 2004). A family of evolutionarily conserved dibasic-specific and monobasic-specific  $\text{Ca}^{2+}$ -dependent serine proteases called subtilisin/kexin-like proprotein convertases (PCs) are responsible for this type of cleavage. In mammals PCs are the major endoproteolytic processing enzymes in the secretory pathway and are involved in processing an extensive number of proteins including peptide hormones, receptors, extracellular matrix proteins, and glycoproteins from infectious viruses and bacterial toxins (Duckert, Brunak et al. 2004). They usually cleave immediately after the consensus sequence [R/K]-X<sub>n</sub>-[R/K] where R represents arginine, K represent lysine, X represents any amino acid, and n represents 0, 2, 4, or 6. One of the aims of this thesis study is to reveal pro-domains recognized by PCs or other proteolytic enzymes in proteins secreted via acetabular secretory vesicles in schistosomes.

### *Signal Peptide Prediction*

Original methods for predicting signal peptides and their cleavage sites used weight matrices (Heijne 1986). More recent methods use neural networks. SignalP, which uses neural networks, was used in this thesis study as it has shown accuracy, specificity, and sensitivity over other non-weight matrix type methods (Bendtsen, Nielsen et al. 2004) including PSORT-II (Nakai and Horton 1999) and SubLoc (Hua and Sun 2001). It uses one neural network to predict signal peptides and another one to predict signal peptidase I cleavage sites. (LipoP predicts signal peptidase II cleavage sites, which are found in lipoproteins (Juncker, Willenbrock et al. 2003).)

In the first version of SignalP (Nielsen, Engelbrecht et al. 1997) data for training the eukaryotic neural networks was obtained from SWISS-PROT version 29 (Bairoch and Boeckmann 1994) and included nonredundant secreted (first 30 amino acids), membrane, cytosolic and nuclear proteins (first 70 amino acids). A total of 1011 proteins from eukaryotes and an additional 416 specifically from humans were used. The network was a feed-forward network, trained using back-propagation. Test performance was determined by using 5-fold cross-validation (data sets were divided in five approximately equal parts and each part was used as a test set while the other 4 parts were used to train the network) and taking an average over each of the five test sets. Correlation coefficients were calculated based on the number of correctly and incorrectly predicted signal peptides. It was found that for the eukaryotic sample set, the correlation coefficient for signal peptide discrimination was .97 and the percent of correctly predicted cleavage sites was 70.2%. Eukaryotic signal peptides were shown to be dominated by Leu with some occurrence of Val, Ala, Phe, and Ile. The subset of human proteins showed no significant difference from the eukaryotic data set in their signal peptides and training the networks on a single species did not improve predictive performance. While the first version of SignalP was quite good at distinguishing between signal peptides and non-signal peptides, it had an error rate of about 5/% in distinguishing between signal peptides and signal anchor sequences, which are often quite similar to signal peptides after their hydrophobic region.

SignalP version 3.0 was used in this thesis study. Improved performance in this version over previous versions of the neural network algorithm was obtained by manually correcting annotation errors contained in training data (1192 eukaryotic sequences from SWISS-PROT), taking into account novel amino acid frequencies and positions for detecting annotation errors that were possibly not removed from training sequences, and implementing a new D-score for classification of signal peptides versus non-signal peptides (Bendtsen, Nielsen et al. 2004). Prediction of signal peptides *versus* non-signal peptides improved from a correlation coefficient of 97 to 98, and prediction of signal peptide cleavage sites improved from 70.2% to 79%.

### *Propeptide/Conserved Motif Prediction*

Motif identification tools have traditionally taken one of two approaches- either alignment methods, which are *sequence-driven*, or enumerative/exhaustive methods which are *pattern-driven* (Ohler and Niemann 2001). Tools that take the alignment approach include CONSENSUS, MEME, and BioProspector. CONSENSUS (Hertz and Stormo 1999) performs a local multiple sequence alignment of all sequences, aligning them one at a time and constructing a weight matrix that optimizes the information content. MEME (Bailey and Elkan 1994), which applies expectation maximization, and BioProspector (Liu, Brutlag et al. 2001), which uses a Gibbs sampling strategy, consider start positions of the motif to be unknown and determine which positions give the most conserved motif by performing a local optimization (Ohler and Niemann 2001). Tools that take the enumerative/exhaustive approach update a nucleotide probability matrix as they evaluate the frequency of occurrence of all possible sequences of length  $n$  using an iterative process. A new approach that claims advantages over existing algorithms employs evolutionary computation (Fogel, Weekes et al. 2004).

MEME, a sequence-driven alignment method, was used in this thesis study. It uses an unsupervised learning approach to searching for motifs in data sets about which very little is known. The only inputs that MEME requires are the set of sequences and the width of motif to search for. It can find several different motifs with differing numbers of occurrences in a single dataset. An algorithm called MM, mixture model, is used to fit a two-component finite mixture model to the set of sequences (Bailey and Elkan 1994). The two components consist of: 1) probability densities of the motif itself and 2) probability densities for all other positions in the sequences, the background. The expectation maximization technique (Aitkin and Rubin 1985) is then applied to the two densities to estimate each of their parameters and the mixing parameter.

A log likelihood ratio is calculated for each column in the motif:

For  $I = 1 \dots n$ , where  $n$  = number of columns in the motif,

$$\text{llr} = \sum \log ( P(\text{site-specific occurrence}|\text{motif})/P(\text{occurrence}|\text{background model}))$$

The first probability in this equation is one of the outputs of MEME, a position-specific probability matrix, or PSPM, which shows probabilities of each amino acid vs. every position in a particular motif. It is based on the set of input sequences. The second probability in the equation is not position-specific. It is based on either the input sequences or any other set of specified sequences.

MEME computes a p-value for the log likelihood ratio ( $\log L$ ) of each column in the motif, instead of a p-value of the sum of the log likelihood ratios, and then arrives at an e-value for the motif by computing the product of the p-values. This makes the e-value reported by MEME an approximation, which is much more efficient to compute, rather than an actual e-value. The e-value corresponds to the number of motifs that would have an equal or higher log likelihood ratio if the training set of sequences had been generated randomly according to the background model. The e-value is also based on the width of the motif, the number of occurrences, the size of the training set, and the type of distribution. MEME outputs the motif with the smallest e-value, represented as a position-specific scoring matrix, PSSM.

Given the missing data  $Z$ , the observed data  $X$ , and the current parameter values,  $\theta = \theta^{(0)}$  and  $\lambda = \lambda^{(0)}$ , the e-value for the first component of the mixture model (the motif itself), is computed as:

$$\mathbb{E}_{(Z|X, \theta^{(0)}, \lambda^{(0)})} [\log L(\theta, \lambda|X, Z)] = \mathbb{E}_{(Z|X, \theta^{(0)}, \lambda^{(0)})} \left[ \sum_{i=1}^n \sum_{j=1}^g Z_{ij} \log(p(X_i|\theta_j)\lambda_j) \right]$$

The e-value for the second component of the mixture model (all other positions in the sequences) is computed as:

$$Z_{ij}^{(0)} = \mathbb{E}[Z_{ij}|X, \theta^{(0)}, \lambda^{(0)}]$$

High log likelihood ratios correspond to low the e-values. Generally the e-value for the motif should be lower than .01 to be considered real.

The total information contained in each motif can be determined by summing up the information contained in each position of the motif. Positions that are highly conserved have high information content (IC, measured in bits), while positions that are not highly conserved have low information content. MEME documentation states that for a motif to be useful for database searches, it must contain at least  $\log_2(N)$  bits of information, where N is the number of sequences in the database being searched. For example, when searching a database of 20,000 sequences for a MEME motif, the IC of the motif should be at least 14.4.

MAST (Bailey and Gribskov 1998) uses the position-specific scoring matrix and threshold produced by MEME together as a Bayes-optimal classifier to search for occurrences of the motif in databases. A match score is computed for each sequence in the specified database. The score for the match of a position in a sequence to a motif is computed by summing the appropriate entry from each column of the position-dependent scoring matrix that represents the motif. The QFAST algorithm (Bailey and Gribskov 1998) is then used to compute the combined p-value of a sequence, which measures the strength of the match of the sequence to all the motifs. It is calculated by 1) finding the score of the single best match of each motif to the sequence, 2) calculating the sequence p-value of each score (defined as the probability of a random sequence of the same length containing some match with a score as good or better), 3) forming the product of the p-values, and 4) taking the p-value of the product. The E-value of a sequence is the expected number of sequences in a random database of the same size that would match the motifs as well as the sequence does. It is equal to the combined p-value of the sequence times the number of sequences in the database. A motif occurrence is defined as a position in the sequence whose match to the motif has position p-value less than 0.0001. The position p-value of a match is the probability of a single random subsequence of the length of the motif scoring at least as well as the observed match.

## *Protein Domain and Gene Ontology Analysis*

Assignment of a particular functional domain and Gene Ontology (GO) terms to a protein can help determine potential relationships to other proteins as well as physiochemical properties. There are multiple and various tools for searching protein fingerprint databases. InterProScan (Mulder, Apweiler et al. 2005) is a tool that unites all protein signature recognition methods and databases of all of its consortium members, making it the most comprehensive tool available. These member databases and methods include ProDom/BlastProDom (Blastall), PRINTS/FingerPrintScan, TIGRFAMs/Hmmpfam, Pfam/Hmmpfam, PROSITE/ScanRegExp + ProfileScan, PIRSF/Hmmpfam, CATH/Hmmpfam, PANTHER/Hmmsearch, SignalPHMM/SignalPHMM, Transmembrane/TMHMM2.0, SMART/Hmmpfam, and SUPERFAMILY/Hmmpfam. The last four listed are not public and so will not be used. InterProScan launches all of these various applications, taking advantage of pre-computed results whenever possible, and then merges all the data together. GO annotation data can also be included in the output of InterProScan and included in the merged result file.

### **C. Research Question**

Are there any significant common motifs among secreted and/or tegumental proteins and, if so, what role do they play in *S. mansoni* secretion?

### **D. Intended Research Project**

The intent of this project is to follow the same workflow that Hiller *et al.* (2004) used to find an export signal in *P. falciparum* sequences. MEME will be used to perform motif analysis on cercarial secretion and adult tegument proteins from *S. mansoni* to determine if a conserved signal is present. If such a signal is found, MAST will be used to search for the motif in public *S. mansoni* databases. Recursive iterations of MEME and MAST will be used to continually optimize the motif and search for it in public databases until the motif cannot be refined further and it is not revealed in any new sequences. Bioinformatic analysis of the motif and the proteins found to contain it will be used to propose a secretion model.

### III. METHODS

#### A. Materials: Software and Hardware

NCBI's BLAST 2.2.1 (Altschul, Madden et al. 1997) was executed on a UNIX server (6-337 MHz processors, 4 Gb RAM, 600 Gb disk space) for performing local sequence alignments to determine sequence similarity. ClustalW (Thompson, Higgins et al. 1994) was executed from the European Bioinformatics Institute's web server (<http://www.ebi.ac.uk/clustalw/>) for performing multiple sequence alignments and generating phylogenetic trees, and SignalP 3.0 (Bendtsen, Nielsen et al. 2004) was executed from the SignalP web server (<http://www.cbs.dtu.dk/services/SignalP/>) for predicting signal peptides. The following software was installed and executed from a UNIX server (2 Xeon 3.5 MHz processors, 4 Gb memory, 1.8 Tb disk space): MEME, Multiple Expectation Maximization for Motif Elicitation, (Bailey and Elkan 1994) version 3.0 for predicting conserved sequence motifs, MAST, Motif Alignment Search Tool, (Bailey and Gribskov 1998) version 3.0 for searching databases for motifs predicted by MEME, and InterProScan version 12.0 (Mulder, Apweiler et al. 2005) for protein domain and Gene Ontology (GO) annotation. The same machine was used to run Matlab 7.0.1 (The Mathworks) for developing a script to compute the entropy of sequence protein domain and GO features. Perl 5.8.4, including the BioPerl module, was used to develop scripts that automate the parsing and reformatting various result files.

## **B. Samples and Subjects**

### **1. Animal or Human Subject Clearance**

This project did not involve any wet lab work; there was no direct contact with the parasite of interest.

### **2. Sample Size**

A total of 177 proteins were analyzed. This included two different sample sets from *S. mansoni* cercarial secretions (Knudsen, Medzihradsky et al. 2005) and one from *S. mansoni* adult tegument (van Balkom, van Gestel et al. 2005) as follows: 1) 81 *S. mansoni* cercarial secretion proteins induced by skin lipid (average length = 423 aa), 2) 53 *S. mansoni* cercarial secretion proteins induced by tail shearing (average length = 347), 3) 43 adult tegument proteins (average length = 224) and 4) 155 full-length *S. mansoni* proteins downloaded from NCBI for use as a control set (average length = 434). To distinguish between the two different sets of cercarial proteins, the 81 proteins from tail shearing induction will be referred to as “vesicles” and the 53 proteins from lipid induction will be referred to as “secretions” hereafter. The vesicles sample set provided the most information as it contains the most sequences, has an average length of sequence that is significantly longer than the other two sample sets, and is the result of a method that minimized contamination, as explained below.

Sequence databases were downloaded for use with the MAST program as follows:

1. 455 full-length *S. mansoni* proteins NCBI’s nonredundant protein database (accessed July 17, 2006)
2. 3894 full-length *S. mansoni* and *S. japonicum* proteins from NCBI’s nonredundant protein database (accessed April 23, 2005)
3. A set of 26,228 assembled EST contigs and singletons from the Schistosoma Genome Network’s SmAE database (Verjovski-Almeida, DeMarco et al. 2003) (accessed September 12, 2005, url: <http://cancer.lbi.ic.unicamp.br/schisto6/>),

4. A set of 33,704 assembled EST contigs and singletons from TIGR's SmGI release 5 (accessed January 22, 2005), *S. mansoni* Gene Index database (Quackenbush, Liang et al. 2000) (url: [http://www.tigr.org/tigr-scripts/tgi/T\\_reports.cgi?species=s\\_mansoni](http://www.tigr.org/tigr-scripts/tgi/T_reports.cgi?species=s_mansoni)).

### 3. Samples

Three different sets of samples were used in this study as listed in Appendix A. Experiments for stimulating, isolating, and identifying the samples were completed previously by Knudsen *et al.* (2005) and van Balkom *et al.* (2005). Those experimental procedures are briefly described here for the purposes of understanding the source of the samples and methods used to induce secretion.

Two sets of samples from *S. mansoni* cercariae were isolated and identified by Knudsen *et al.* (2005). In summary, the first set of samples was collected from cercariae after vesicle secretion was stimulated by mechanical tail shearing, artificially transforming the cercariae into schistosomula. After cercariae were pushed through a small syringe, which forced their tails to be sheared, they were allowed to secrete for 1.5-2.0 hours on a Petri dish containing culture medium, medium was removed from the plate, and vesicles that were left behind on the Petri dish were collected. This method resulted in a set of samples that had minimal contamination with snail, lettuce, and human proteins from the lab environment. The second set consists of samples isolated after cercariae were exposed to human skin lipid, the parasite's natural biological stimulus, on a Petri dish for 1.5-2.0 hours in warm water. Their secretions were separated from the cercarial bodies and tails through centrifugation. The proteins in both the first and second sample sets were isolated and sequenced using 1D SDS PAGE, in-gel digestion, and LC-MS/MS. Data was analyzed using Analyst QS software (Applied Biosciences) with Mascot (Matrix Science, London, UK) and then identified using Mascot server version 2.0.01 to search both the nonredundant protein database at NCBI (September 8, 2004) and a six-frame translation of TIGR's SMGI database, version 5. These sample sets will be referred to hereafter as "vesicles" and "secretions", respectively.

The third set of samples was isolated from the adult schistosome tegument as described by van Balkom et al. (van Balkom, van Gestel et al. 2005). Briefly, the tegument surface membranes of adult worms was “stripped” through a series of steps that included washing, freezing, applying vortex pulses, passing the tegument membrane-containing supernatant over a fine stainless steel mesh, and centrifuging the filtrate to collect the tegument membrane. Proteins contained in the tegument membranes were then isolated and sequenced using both 1D and 2D SDS PAGE, in-gel digestion, immunoblotting, LC-MS/MS, and MALDI TOF-TOF (applied to proteins excised from 2D gels only). They were then analyzed using ProteinLynx Browser version 2.1 software (Micromass), and identified by searching a six-frame translation of TIGR’s *S. mansoni* Gene Index database version 5 with Mascot software (Matrix Science, London, UK). Proteins that could not be identified using TIGR’s database were identified using the *S. mansoni* GeneDB where possible (El-Sayed, Bartholomeu et al. 2004). This sample set will be referred to hereafter as “tegument”.

A set of control proteins were derived by searching NCBI’s nonredundant database for full-length *S. mansoni* cDNA sequences, downloading the resulting 686 sequences, translating them to protein, and using them as both the query and subject sequences in a BLAST search. BLAST results determined that 531 sequences were either identical or highly homologous to other sequences. These were removed from the data set, resulting in 155 nonredundant proteins that were used as a control set.

### **C. Procedures and Interventions**

As outlined in Figure 7, Workflow #1, sequences were analyzed for the presence of ER-type signal peptides using SignalP and propeptides using MEME and MAST. Initial sequences were obtained by searching either NCBI’s nonredundant protein database or TIGR’s SmGI database for accession number provided in the two papers “Proteomic Analysis of *Schistosoma mansoni* Cercarial Secretions” (Knudsen, Medzihradszky et al. 2005) and “Mass Spectrometric Analysis of the *Schistosoma mansoni* Tegumental Subproteome” (van Balkom, van Gestel et al. 2005). TIGR’s database provided nucleotide

sequences and several different corresponding translations including an ESTScan translation (Iseli, Jongeneel et al. 1999), FrameFinder translation (Slater 1996-1999) and a six-frame translation. The best translation (i.e. best alignment between query sequence and subject sequence) was determined using a manual BLAST (Altschul, Madden et al. 1997) search against NCBI's nonredundant protein database. In some instances protein translations were not provided by TIGR, in which case a Perl script was used to translate the DNA sequence into six frames and the longest frame was selected and verified using BLAST.

Sequences were analyzed using SignalP version 3.0 (Bendtsen, Nielsen et al. 2004) to determine if they contain an N-terminal signal sequence. Presumably these are the sequences targeted for export via a traditional extracellular secretion model. SignalP will be set to run both its neural network trained on eukaryotic sequences and input sequences will be trimmed to 100 amino acids.

Proteins from each sample set were submitted to MEME (Bailey and Elkan 1994) to search for conserved motifs. Sequences containing a predicted signal peptide were submitted separately from those without one. Proteins with a predicted signal sequence were trimmed to 100 bases from the cleavage site predicted by SignalP before submission to MEME. If MEME found a statistically significant motif, the resulting motif file (PSSM) was used by the MAST program (Bailey and Gribskov 1998) to search three databases for the motif: 1) full-length *S. mansoni* and *S. japonicum* protein sequences from NCBI's nonredundant protein database, 2) SmGI (Quackenbush, Liang et al. 2000), and 3) SmAE (Verjovski-Almeida, DeMarco et al. 2003) for the same motif. If the motif was found in additional sequences, those sequences were combined with the ones that MEME originally found to contain the motif, and all sequences were run through MEME again to refine the initial motif. Recursive iterations of submitting sequences to MEME and motifs to MAST were performed until the motif could not be refined any further and was not found in any additional sequences. To validate these methods, identical materials and processes were followed as those employed by Hiller *et al.* to elucidate a conserved motif in *P. falciparum* and the end results were compared.

A complimentary workflow was also executed, as outlined in Figure 8, Workflow #2. To determine the amount of overlap of proteins between data sets as well as within a single data set (to determine diversity), sequence alignment methods were applied. BLAST (Altschul, Madden et al. 1997) was used to perform local alignments and CLUSTALW (Thompson, Higgins et al. 1994) was used to perform multiple sequence alignments. The alignment file resulting from the CLUSTALW alignment of each sample set was used to generate a phylogenetic tree, which was visualized using JalView (Clamp, Cuff et al. 2004). InterProScan (Mulder, Apweiler et al. 2005) was used to predict protein domains and GO terms for the *S. mansoni* cercarial secretome and adult tegument proteins. Scripts were written to process the InterProScan raw data to generate counts and percentages of protein domains and GO terms represented in each sample set, as well matrices of sequences *versus* protein domains and sequences *versus* GO terms. A Matlab script was written to calculate entropy and information gain for each feature within a dataset to determine the most significant protein domains and GO terms. These methods provided means for comparing and contrasting proteins enriched in the different sample sets for improved understanding of the set of functions used by the invading parasite.

#### **D. Statistical Analysis**

Expectation and probability scores resulting from MEME and MAST were used to determine the validity of motifs found. A Matlab script was used to calculate the entropy of protein domain and GO annotation data, from which the most significant features in each data set were determined.

#### **E. Expected Results**

The expectation is that iterative use of MEME and MAST will elucidate a common motif across multiple *S. mansoni* cercarial secretion and/or adult tegumental proteins downstream of an ER-type signal sequence. This motif will be used to infer a proposed model for the mechanism of secretion in schistosomes.

## **F. Alternate Plans**

If reiterative use of MEME and MAST does not reveal a conserved motif, alternative methods for finding conserved motifs will be applied, such as multiple sequence alignment, ProP (Duckert, Brunak et al. 2004), and alignment using sequence logos. Functional annotation methods will also be further improved and automated.

Annotation (BLAST, Protein Domain, GO) and statistical analysis of annotation

## IV. RESULTS

### A. Introduction

Detailed and summary results are provided in the following Specific Findings result section. Results are presented in the following order: 1) signal peptide analysis, 2) results of method validation, 3) a detailed explanation of steps followed in the motif analysis and summary results, 4) homology analysis, 5) protein domain and GO annotation data, 6) statistical analysis of annotation data including the most significant domains and GO terms.

### B. Important Highlights

Reiterative use of MEME and MAST yielded a proposed conserved sequence motif of x[K/R]xGE across 11 sample proteins and 2 proteins from *S. japonicum*. The vesicles were enriched for the motif. An effort to reproduce the workflow followed by Hiller *et al*, which resulted in discovery of a conserved motif across *P. falciparum* proteins, was only successful after manual manipulation of the N-terminal starting positions of the initial five protein sequences used in that analysis. The use of a stringent background model was found to be important to the success of MEME searches. Interestingly, the sample proteins had a significantly lower percentage of predicted signal peptides. Methods were developed for quickly creating matrices of protein domains or GO terms *versus* protein names. These matrices provided a way for comparing proteins to determine similarities and differences. They were useful in determining functional differences in the lipid-induced proteins *versus* the tail shearing-induced proteins, and in evaluating proteins proposed to contain a conserved motif. Statistical methods for determining the most statistically significant domains and GO terms were also automated and applied. It was determined that ATP binding was the most represented biological function in the vesicles, at a level 2-1/2 times higher than in the secretions, and glycolysis was the most represented biological process in the secretions.

## C. Specific Findings

### *Signal Peptide Prediction*

Table 1 below provides SignalP neural network predictions of signal peptides and cleavage sites for each of the sample sets. Figure 9 gives a summary comparison of the three different sample sets by showing the total number of proteins in each sample set and the total number of proteins that contain a signal peptide in each sample set. All sample sets had relatively low numbers of sequences that were predicted to contain a signal peptide. 11%, 9%, and 7% of vesicles, secretions, and tegument proteins respectively were predicted to have signal peptides. By contrast, 36 of 155 control proteins, or 23% were predicted to contain a signal peptide. It was expected that a higher number of the secreted proteins contained in the vesicles, secretions, and tegument proteins would have a signal peptide than the control proteins. Possible reasons for this discrepancy will be discussed later.

Figure 9. Comparison of 3 Sample Sets

Table 1. Signal peptide predictions

Tables below show SignalP neural network prediction results. Note: Only positive results are shown for the control samples. Two neural networks are used by SignalP: one to predict the actual signal peptide and one to predict the cleavage site. S-score: calculated for every amino acid in the submitted sequence; a high S-score for an amino acid is an indicator that it is part of a signal peptide. S-mean is the average of the S-score and is calculated for the length of the signal peptide. C-max: measure of the likelihood of an amino acid being part of the cleavage site; calculated for every amino acid in the submitted sequence; the amino acids with the highest C-max scores are predicted to be part of the cleavage site. Y-max: derived from a combination of the C-max score and S-mean score. D-score: a new scoring method in version 3.0, the average of the S-mean and Y-max scores. It outperforms S-score for discriminating between signal peptides and non-signal peptides (Bendtsen, Nielsen et al. 2004).

### *Method Validation*

To validate the methodology used by Hiller *et al.* (Hiller, Bhattacharjee et al. 2004) to find and refine a conserved sequence motif, an attempt was made to reproduce the authors' workflow using the same exact samples and methods. A pattern had initially been identified by using MEME to analyze the first 100 residues of five *P. falciparum* sequences, known to be vacuolar transport sequences, starting immediately after the predicted SS cleavage site. To validate this, the five sequences were downloaded from the nonredundant protein database and submitted to SignalP for signal peptide prediction. Interestingly, only three of the five sequences were found to contain a signal sequence using the neural networks method (and only two of five using the hidden Markov model method). When just these three sequences were trimmed to 100 residues after the predicted cleavage site and submitted to MEME, the same motif found by Hiller *et al.* was not found. The other two sequences were added into the analysis and submitted to MEME in an attempt to discover the same motif. But only after manipulation of the starting point of the sequences was the same motif found. The rest of the workflow was not difficult to validate. This leads to two points: 1) finding conserved motifs with MEME when the initial number of input sequences is small, is not trivial, and 2) finding a motif using MEME is likely to be more successful when it is complimented by lab experiments. Hiller *et al.* had the benefit of prior experimental knowledge of exactly which amino acids were required for a protein to be exported.

### *Conserved Motif Analysis*

By default, MEME uses the input sequences to build a 0-order Markov model of amino acid frequencies for use as a background model in determining the likelihood of particular motifs. It follows that when the number of input sequences is small, the background model is not as sensitive as when the number of input sequences is large. To improve the sensitivity of the search and provide a consistent background for each analysis, a background model was built based on amino acid frequencies of the control set. The

control set consisted of 155 full-length *S. mansoni* cDNA sequences downloaded from NCBI, from which redundancy and highly homologous sequences had been removed. This model was specified as the background in all MEME searches in place of the input sequences. In the control set, shown on the left in Figure 10, amino acids Cys (C), Phe (F), His (H), Ile (I), Asn (N), Ser (S), Thr (T), Trp (W), and Tyr (Y) are enriched, with Asn (1.7% difference) and Ser (2.1% difference) being the most significantly different. In the vesicle data set, shown on the right in Figure 10 below, amino acids Ala (A), Asp (D), Glu (E), Gly (G), Lys (K), and Val (V), with Ala (2.1% difference) and Glu (2.0% difference) being the most significantly different.

used as background in MEME analysis;  
Right: Amino acid frequencies of vesicles data set

Without either elimination or careful weighting of overrepresented proteins, the motif analysis led to false positives that were due to high sequence homology, not necessarily to common secretion function. Sequences that had high homology to other input sequences were weighted equally by specifying weights in the first line of the fasta input file as follows. For example, if two highly homologous sequences existed in the file, the first line of the input file contained the line: “>WEIGHTS 0.5 0.5” followed by the two highly homologous then all other sequences.

In order to increase the sensitivity of the search when the number of input sequences to MEME was small (twenty or fewer), parameters were set to assume that each sequence in the data set contained *exactly one* occurrence of each motif and to search for a motif that is five amino acids wide, corresponding to the following example command line: `meme -inputfile.fasta -bfile Sm_nr_155.txt -mod oops -w 5 >output.html`. The increased speed and sensitivity of this search sacrifices accuracy and may result in fuzzy motifs. When the number of input sequences was not small (greater than twenty), MEME parameters were set to assume that each sequence contains *at most one* occurrence of each motif (since it is likely that some may not contain the motif) and to allow MEME to automatically choose the best motif width (the default). These settings correspond to the example command line: `<meme -inputfile.fasta -bfile Sm_nr_155.txt -mod zoops >output.html>`. While this option is slower and slightly less sensitive to weak motifs, it results in more accurate motifs.

MEME output includes (as labeled in Figure 11): A) an information content (IC) diagram, B) a simplified PSPM, C) a multilevel consensus sequence, D) a block diagram of the occurrence of the motif in each training/input sequence, and E) the occurrences of the motif. In the IC diagram, the positions with the highest IC are the most conserved. The most hydrophobic amino acids are colored blue, while polar, non-charged, non-aliphatic residues are colored green, acidic residues are magenta, and positively charged are red. Other residues are various other colors. The simplified PSPM gives the probability of each possible letter appearing at each possible position in an occurrence of the motif. For readability the letter probabilities are multiplied by 10 and rounded to the nearest integer, where 10 is replaced by “a” and zeros are replaced by “:”. The multilevel consensus sequence is calculated from the PSPM. The most likely motif is on the first line and any letter substitutions that have a probability greater than .2 are shown in lines below it. The block diagram shows all occurrences of the motif in each sequence, sorted by the lowest p-value. It can be used to compare relative motif positions across sequences. The p-value of an occurrence is the probability of a single random subsequence the length of the motif,

generated according to the 0-order background model, having a score at least as high as the score of the occurrence. The diagram of the occurrences of the motif within each sequence shows the exact motif found in each sequence. It can be used to get a view of how conserved the motif is across sequences.

When the nine vesicle proteins that were predicted to contain an ER-type signal sequence were submitted to MEME, a conserved motif of [E/L]K[H/R]GE resulted, with the K, G, and E residues being the most conserved, as shown in Figure 11, MEME #1. The input sequences (Table 2) included 1) three highly homologous elastases, 2) an endoplasmin and a surface protein that showed 20% homology in a BLAST comparison, 3) four other proteins that had no homology to any other sequences within this subset or the entire vesicle sample set: calreticulin, PDI, a SPO-1 protein, and an unidentified protein. They were trimmed to start at their predicted signal peptide cleavage site and extend 100 amino acids. The three elastases which shared 80% to 92% sequence identity were each weighted equally at 33.3% to eliminate bias caused by overrepresentation of these proteins.

The motif elucidated in MEME #1 contains 13.6 bits of information, an e-value of 770 and a log likelihood value of 85. The motif starts with a positively charged residue, lysine (K), and ends with an acidic residue, glutamic acid (E). Inspection of the occurrences of the motifs shows that it exists across calreticulin, endoplasmin, PDI, and the elastases. Arginine substitutes for lysine in the elastases. The motif does not exist in the SPO-1 protein (AAD26122), the surface protein (T30271), or the protein annotated as similar to B-cell receptor associated protein (T10689).

Figure 11. MEME #1

xKxGE motif: information content = 13.6; e-value = 770; log likelihood ratio = 85

The first MAST search using this motif was against a database of 455 full-length *S. mansoni* proteins downloaded from NCBI's nonredundant protein database. A database containing 455 sequences requires that the motif has at least  $\log_2(455)$  bits of information (as discussed on page 42). This corresponds to 8.8 bits, hence the motif is significant enough for the search. Results of MAST search #1 are shown in Figure 12.

MAST motif diagrams show all motif occurrences. A motif occurrence is defined as a position in the sequence whose match to the motif has position p-value less than .0001. The *position* p-value is equal to the probability that a single random *subsequence of the length of the motif* scoring at least as well as the observed match. The score is computed by summing the appropriate entry from each column of the PSSM. The *sequence* p-value of a score is defined as the probability of a *random sequence of the same length* containing some match with as good or better score. The combined p-value of a sequence (p-value of the product of the sequence p-values) measures the strength of the match of the sequence to all motifs. The e-value of a sequence (combined p-value of the sequence times the number of sequences in the database) is the expected number of sequences in a random database of the same size that would match the motifs as well as the sequence does and is equal to the.

Figure 12 shows that there were 24 sequences with e-values less than 10 resulting from the first MAST search (MAST #1). This included eleven different proteins. Outlined in blue are five proteins that existed in the original data set used in MEME #1 and outlined in red are six new proteins that did not. The new ones include: thioredoxin peroxidase, thioredoxin, myosin light chain, calcium binding protein, immunophilin, and AUT1. Thioredoxin peroxidase is found across all sample sets, thioredoxin is unique to the secretions, myosin light chain is unique to vesicles, calcium binding protein exists in both vesicles and secretions, and immunophilin and AUT1 are not contained in any of the sample sets. Figure 13 depicts relative positions of motifs in order of increasing e-value. The motif occurs in a different position for each protein.

Figure 12. MAST #1 high scoring sequences

Input: motif from MEME #1 & 455 full-length *S. mansoni* proteins NCBI's nonredundant protein database

Proteins not contained in original input sequences (used in MEME #1) are outlined in red, proteins contained in the original input sequences are outlined in blue. Redundant proteins are not outlined.

Figure 13. MAST #1 motif diagram

Input: motif from MEME #1 & 455 full-length *S. mansoni* proteins NCBI's nonredundant protein database

Motifs with significant position p-values (<.0001) are indicated by "1".

To refine the proposed motif using an additional iteration of MEME, the six new proteins (outlined in red in Figure 12) were added to the set analyzed in MEME #1 (vesicle proteins containing signal peptides). Two of the three redundant elastases were removed from the input sequences so that the input contained only unique sequences. If sequences contained a signal peptide, they were trimmed to start at the signal peptide and extend 100 amino acids. If they did not contain a signal peptide, the entire sequence was used. Sequences used as input to MEME #2 are shown in Table 3 below.

Figure 14. MEME #2

xKxGE motif: information content = 13.3 bits; e-value = .0059; log likelihood ratio = 120

Results of MEME #2 are shown in Figure 14. The consensus sequence changed slightly but the most conserved residues remained unchanged: xKxGE. This motif contains 13.3 bits of information and had an e-value of .0059 (improved from 770 in MEME #1) and a

log likelihood ratio of 120 (improved from 85 in MEME #1). Given that for a motif to be considered real it needs to have an e-value below .01, this motif can be considered valid. 13.3 bits of information is sufficient to search databases containing approximately 10,000 or fewer sequences ( $\log_2(10000)=13.3$  bits), so this motif could not be used to search the entire SMGI or same, or nr databases, but it could be used to search smaller sets of proteins.

Two additional MAST searches were performed. MAST #2 (Figures 15 and 16) was executed using the motif from MEME #2 to search a subset of NCBI's nonredundant protein database containing ~4000 full-length *S. mansoni* and *S. japonicum* sequences including the 455 *S. mansoni* sequences contained in the database used in the first MAST search. The motif was found in many of the same proteins as in MAST #1: thioredoxin, thioredoxin peroxidase, myosin light chain, calreticulin, calcium binding protein, and immunophilin. It was also found in 10 *S. japonicum* sequences. AAW26398 has 97% identity to myosin light chain which is found in vesicles (AAD41591), AAW25436 has 88% identity to *S. mansoni* thioredoxin peroxidase 3 (AAG15509), AAW25625 is *S. japonicum* thioredoxin peroxidase 2 (BAD90102), and AAW27121 has 78% identity to *S. mansoni* immunophilin (AAB05213). The other *S. japonicum* sequences the motif was found in either lack homology to any other sequence or are homologous only to unknown proteins. The motif occurs between amino acids 40 and 105 in immunophilin, myosin light chain, thioredoxin, calreticulin, and calcium binding protein. It occurs outside this range, starting between amino acid 60 and 90, only in thioredoxin peroxidases (AAD17299, AAG15507, AAG15507, AAD40685, AAW25625 and AAW25436) and unknown *S. japonicum* proteins (AAW25402 and AAW24755).

Figure 15. MAST #2 high scoring sequences

Figure 16. MAST #2 motif diagram

Input: motif from MEME #2 and ~4000 full-length *S. mansoni* and *S. japonicum* sequences

Motifs with significant position p-values (<.0001) are indicated by "1".

Another MAST search, MAST #3, Figures 17 and 18, was executed using MEME motif #2 to search all original vesicle, secretion, and tegument proteins. Exact duplicate sequences were eliminated from this database resulting in a total of 130 proteins. Proteins with position p-values less than .0001 appear in the motif diagram in Figure 18. These include: thioredoxin, thioredoxin peroxidase 1a, thioredoxin peroxidase 2, myosin light chain, calreticulin, calcium binding protein, SPO-1 protein, PDI, endoplasmin, elastase 1b, phosphoglycerate mutase, and malate dehydrogenase. Elastase 1b, phosphoglycerate mutase, and malate dehydrogenase were new proteins, not discovered in previous MAST searches.

For each sample protein predicted by MAST to contain the proposed conserved motif, Table 4 (above) provides details about the motif prediction as well as signal peptide prediction, where applicable. Only three of the eleven proteins (27%) were predicted to contain a signal peptide by SignalP. These eleven proteins were further analyzed for signal peptides with SIGCLEASE (Peter Rice, European Bioinformatics Institute, 1989). SIGCLEASE uses the von Heijne method to distinguish signal peptides from non-signal peptides (95% accuracy) and to predict the cleavage site (75-80% accuracy). This analysis predicted that five of the eleven proteins had signal peptides: the same three predicted by SignalP and also thioredoxin and elastase 1b.

The SPO-1 protein does not actually contain the xKxGE motif. Starting in position 97 the amino acid sequence xKxME exists (shown in red in Table 4 ). It is not likely that methionine can substitute for glycine. Other SPO-1 sequences were evaluated to ensure the difference was not due to sequencing error and they were found to also xKxME instead of xKxGE. Hence, SPO-1 was not considered to contain the motif and not included in further analyses. CLUSTALW analysis of the remaining eleven proteins and two additional public domain proteins found to contain the xKxGE motif was performed. The resulting multiple sequence alignment, which has gaps removed, is shown in Figure 19. Predicted signal peptides are underlined in red. Cleavage sites are at the C-terminal of the signal peptide. The downstream conserved motif predicted by MEME and MAST is underlined in blue for each protein. MEME/MAST does not provide cleavage site predictions.

The alignment shows that the motif is predicted to occur at positions 261-265 in malate dehydrogenase, a protein that is 329 amino acids long. Given the predicted position and the fact that the e-value of the motif in malate dehydrogenase was higher (2.2) than for any of the other eleven proteins, it is unlikely that the motif is not real in that protein. Phosphoglycerate mutase also has the motif in an unlikely position- amino acid 9-13. This does not leave room for a signal peptide to target the protein to the ER. (It was verified using BLAST that the N-terminal of the protein was included.) These two proteins were not considered in further analyses to have the motif of interest.

Figure 19. Multiple sequence alignment of sample proteins with the predicted xKxGE motif (CLUSTALW alignment with gaps removed)

Elastase, of which there are many isoforms, is well-known to be secreted by *Schistosoma* during human invasion. The xKxGE motif was only found in one of the three isoforms identified in vesicles and/or secretions (elastase 1b) and it was found in an unlikely position- 186. Results from MEME #1 (page 65), however, show that in all three elastases contained in the sample proteins (AAC46967, A28941, and AAM43941), a motif of xRxGE exists starting two amino acids downstream of a signal sequence. Theorizing that the motif is a proprotein convertase recognition site and considering the fact that, at least in mammals, proprotein convertases (PCs) are known to cleave immediately after a consensus sequence that starts with either K or R (discussed on page 36), we can extrapolate that arginine (R) substitutes for lysine (K) in the second position of our proposed conserved motif in elastases. Figure 19 shows the motif IRSGE in elastase 1b (AAC46967) underlined in a dotted blue line starting in position 27, and the motif predicted by MEME/MAST underlined in a solid blue line starting in position 186.

Based on all MEME and MAST analyses, two additional *S. mansoni* proteins not contained in any of the sample groups contain the motif: immunophilin and AUT1. Immunophilin has 88% identity to an *S. japonicum* protein identified only as SJCHGC01391. It is not predicted to contain a signal peptide but has the conserved motif EKHGE starting at amino acid 66. Two *S. mansoni* AUT1 proteins exist in NCBI's nonredundant protein database, but only have homology to unidentified proteins. AUT1 was also predicted not to have a signal peptide. It has the conserved motif SKRGE starting at position 40.

If, based on the above findings, SPO-1, malate dehydrogenase, and phosphoglycerate mutase are eliminated from those proteins we consider to have the conserved motif, and all three elastases *are* considered to have the motif, a total of 11 sample proteins and 2 non-sample proteins are included, as summarized in Figure 20. 10 of 81 (12.3%) vesicle proteins, 6 of 53 (11.3%) secretion proteins, and only 1 of 43 (2.3%) tegument proteins contain the motif. As the diagram shows, all 6 proteins contained in secretions that have the motif are also contained in vesicles- none are unique to secretions. However, 4 of the 10

proteins in vesicles found to have the motif *are* unique to vesicles. Hence, the motif is enriched in the vesicles.

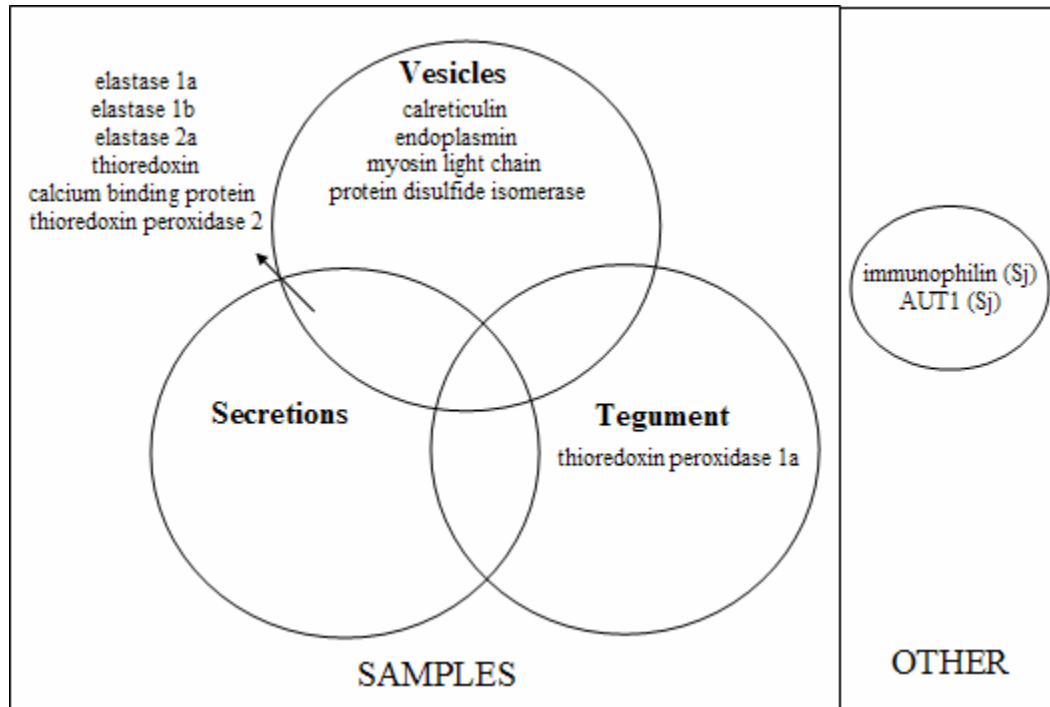

Figure 20. Distribution of proteins found to contain xKxGE motif.

Based on MAST #3

The sequences with the motif but without a predicted signal sequence were analyzed further to determine if the reason no signal sequence was predicted was because the N-terminus of the sequence was missing. A BLAST search against NCBI's nonredundant protein database was performed using each of these sequences and the starting positions of the query sequence and homologous sequences were compared. Myosin light chain, for example, was predicted not to contain a signal peptide. The top five BLAST hits for myosin light chain are shown in Figure 21. In four of the five hits the homology between the query sequence and subject sequence starts at position 1 or position 2. But in the second hit to myosin light chain in *Eisenia fetida* the homology starts at position 1 of the

Figure 21. Top five BLAST hits for myosin light chain AAD41591

subject sequence that had a different N-terminal portion than the query sequence, the subject sequence was submitted to SignalP for signal peptide prediction. But in each case, SignalP results still indicated the lack of a signal peptide.

The logo for the proposed conserved motif, below in Figure 22, shows the relative conservation of each amino acid in the motif. The second, fourth, and fifth residues are most conserved corresponding to lysine (basic), glycine (nonpolar), and glutamic acid (acidic). This corresponds to an enrichment of Lysine, Glutamic Acid, and Glycine residues in the vesicles over the control data set. Interestingly, the motif does have features in common with a conserved motif found in *P. falciparum*, shown in Figure 23. The first most conserved residue in both motifs is a basic amino acid: lysine in *Schistosoma* and arginine in *Plasmodium*. The last most conserved residue in both motifs is glutamic acid. The central most conserved amino acids differ across the two, although there are amino acids with nonpolar side chains in both: in *Schistosoma* glycine is conserved, and in *Plasmodium* lysine and alanine are conserved. One difference is that serine, which has an uncharged polar side chain, is somewhat conserved in *Plasmodium*.

Figure 22. WebLogo of motif found in *S. mansoni* sample proteins  
(Crooks, Hon et al. 2004)

Figure 23. WebLogo of motif in *P. falciparum*.  
(Crooks, Hon et al. 2004) Found across ~320 soluble and insoluble proteins that are exported across the PVM into the red blood cell (Hiller, Bhattacharjee *et al.* 2004).

Further analyses were performed in an effort to determine the possible functions of this motif. Based on the positions of the motifs and signal peptide prediction by SignalP, the motif is not a signal peptide. It was also determined to not be a glycosylation site, a protease site, a phosphorylation site, or an elastase recognition motif. BLAST searches determined that the set of proteins containing the motif do not have any significant homology to each other (Appendices C and D), hence MEME is not simply finding regions of homology across the proteins. Some propeptide convertases are known to cleave on the C-terminal side of sites composed of single or paired basic amino acids; it is possible that the motif is a propeptide that is cleaved on the C-terminal side of the second position of the motif, lysine or arginine (K/R).

Proteins containing the motif were submitted to ProP, a propeptide predictor based on neural networks (Duckert, Brunak et al. 2004). The general propeptide convertase-specific network was used, which was trained on 235 cleavage sites and 1072 negative sites from the SWISS-PROT protein database. It is important to note that the training sequences did not contain any *Schistosoma* sequences. The sensitivity of the network is 61.7, the specificity is 59.7, and the correlation coefficient is .60. Appendix E contains the positive results from this prediction method. 9 of the 14 proteins (64%) containing the motif predicted by MEME/MAST were predicted to have one or more propeptides by ProP: the three elastases, the two thioredoxin peroxidases, calcium binding protein, calreticulin, phosphoglycerate mutase, and AUT1. ProP only predicted the same motif/position for

calcium binding protein that MEME/MAST predicted: NKRGE starting at position 100. Given the relatively low sensitivity and specificity of the ProP predictor, the MEME/MAST results were considered authoritative over the ProP results.

In order to determine how the proposed conserved motif fits into a secretion model, it is necessary to better understand the functions of the proteins that contain it. All sample proteins were functionally annotated with protein domains and GO terms using InterProScan. Methods were developed for transforming the data into matrices of protein domain and GO annotations versus sequence identifiers/descriptions, as explained under *Protein Domain/Gene Ontology Annotation and Statistical Analysis*. Smaller matrices containing the subset of sample proteins containing the proposed conserved motif were extracted from the larger matrices and are shown in Tables 5 and 6. These matrices provide a quick visualization of protein domains and GO annotations that the proteins do and do not have in common. They also give a starting point for more detailed analysis.

The domain matrix in Table 5 shows that several of the proteins have domains in common: 1) both the calcium binding protein and myosin light chain have an EF-Hand motif, 2) both thioredoxin and PDI have a thioredoxin-related domain, and 4) thioredoxin peroxidase 1a, thioredoxin peroxidase 2, thioredoxin, and PDI have a thioredoxin-like fold. The GO annotation matrix in Table 6 shows the following: both endoplasmic reticulum chaperones are involved in protein folding; calcium binding protein, myosin, and calreticulin are all involved in calcium ion binding; thioredoxin and PDI are involved in electron transport activity; and the elastases are involved in peptidase activity.

AUT1 (AAF82607, not included in Tables 5 or 6) contains a Hyaluronan/mRNA binding protein domain (IPR006861), which includes a family of proteins that have been shown to bind hyaluronan, a glucosaminoglycan. Immunophilin (AAA67867, not included in tables 5 or 6) contains a peptidylprolyl isomerase domain (IPR001179) as well as three tetratricopeptide-related domains (IPR001440, IPR11990, IPR13026). The peptidylprolyl isomerase domain is involved in accelerating protein folding by catalyzing the cis-trans

isomerization of proline imidic peptide bonds in oligopeptides. The tetratricopeptide-related domains mediate protein-protein interactions and the assembly of multiprotein complexes. They are involved in a variety of biological processes including peroxisomal protein transport and protein folding.

Interestingly, endoplasmin, calreticulin, and PDI have historically all been known to reside in the ER lumen. Such ER-residing proteins are usually distinguished by the presence of the sequence KDEL at the C-terminal. This sequence does indeed exist at the C-terminal of PDI. In endoplasmin the C-terminal sequence is KDEL and in calreticulin the C-terminal sequence is HDEL. It has been shown, however, that PDI and endoplasmin can be secreted via the normal secretory pathway even when they contain an ER-retention signal (Takemoto, Yoshimori et al. 1992) and PDI has also found to be more highly concentrated in secretory cells (Edman, Ellis et al. 1985). It has been found that the active site of PDI closely resembles that of the redox protein thioredoxin and, therefore, may catalyze disulphide bond formation (Freedman R. B., Hirst T. R. et al. 1994).

To determine the relatedness of proteins within a sample group, a phylogenetic tree was also constructed for each sample group using CLUSTALW as explained under *Homology Analysis*. The complete phylogenetic trees are shown on pages 104-106. Proteins were assigned to phylogenetic groups as labeled on the trees according to the natural groups they would fall into if the tree was cut just below the main branch. The tables on pages 107-115 provide details about the functions related to the proteins contained in each phylogenetic group for each sample set.

Phylogenetic groupings, domains and GO terms are summarized in Table 7 for the vesicle and secretion proteins containing the proposed conserved motif. It shows that all of the proteins except the elastases belong to the same major phylogenetic group, 1. Five of the proteins belong to 1a, one belongs to 1d, one belongs to 1g, and the elastases belong to group 2. Phylogenetic group 1a is related to unfolded protein binding, calcium ion binding, motor activity, and electron transporter activity. Group 1d is related to electron

transporter activity, glycolysis, and gluconeogenesis. Group 1g is related to a diverse set of functions including glycolysis, carbohydrate metabolism, protein polymerization, and protein folding. Group 2 corresponds to peptidase activity.

Considering all detailed annotation data together it is possible to theorize about the functions of the proteins containing the xKxGE motif. It was found in proteins related to calcium binding and regulation, protein folding, and protease activity. Calreticulin is implicated in a large and diverse number of functions. One of its key functions in *Schistosoma* cercaria may be to bind to the clathrin coat of the vesicles while still in the Golgi apparatus. Perhaps it also plays a role in the uptake of other proteins into the vesicles. Once inside the vesicles calreticulin likely plays a role in protein folding along with several other proteins. Myosin light chain and calcium binding protein are likely involved in motor activity that propels the vesicles out of the acetabular glands and guides them to their target epidermal cells. The proteins with calcium binding domains, which include calcium binding protein, myosin, and calreticulin, are likely to be important in the initial binding to target epidermal cells. PDI, endoplasmic reticulum chaperone, and the two proteins not in the samples but found in *S. japonicum*, immunophilin and AUT1, all have chaperone activity, which promotes proper protein folding to prevent protein aggregation and degradation by proteases. Though AUT1 was not found in the sample proteins, domain analysis indicates it has functions in common with calreticulin, and the proposed motif occurs in the same position in these two proteins. Thioredoxin and PDI, as discussed, are likely to function as catalysts for disulfide bond formation. The thioredoxin peroxidases are involved in oxidation of thioredoxin and have antioxidant activity which likely helps protect the secreted proteins from damage during human host invasion. Finally, the elastases have peptidase activity which is directly related to breaking down various layers of human host epidermal tissues.

Table 5. Proteins containing predicted conserved motif vs. protein domains

0 indicates the protein does not contain the corresponding domain, 1 indicates the protein does contain the corresponding domain.

### *Homology Analysis*

To determine the level of identity within and across sample sets, BLAST searches were performed using each sample set as the query against either itself or a different sample set. The blastp program was used with the default settings. A Perl script was used to parse all hits where the total length of the high scoring pair (HSP) was greater than 100, the hit significance was better than  $1 \times 10^{-05}$ , and the percent identity was greater than 50%. Results are shown in Appendices D (homology within sample sets) and E (homology across sample sets).

None of the sample sets has a high level of identity within it. Within the vesicle proteins there are three elastases with 80% or greater homology to each other and three other proteins with 55% - 66% homology to each other, including tropomyosin, thioredoxin peroxidase, and a 14-3-3 protein homolog. Within the secretion proteins, the same three elastases exist and also two peptidyl-prolyl cis-trans isomerase proteins with 57% homology to each other. Within the tegument proteins there are two unidentified proteins with 74% homology to each other.

Two of fifty three secretion proteins showed ~99% homology to tegument proteins; these were thioredoxin peroxidase and ATP dephosphohydrolase I. Similarly, two of eighty one vesicle proteins had high homology to tegument proteins- thioredoxin peroxidase and fimbrin. Two other vesicle proteins, a major egg antigen and an unidentified protein, showed about 50% homology to two unidentified tegument proteins. These intersections are illustrated in Figure 24.

Considerably higher homology was found between vesicle and secretion proteins, as expected. Of the 53 secretion proteins, 41, or 77% were identical to vesicle proteins. Homology between the other proteins was not high. There are several proteins unique to either secretions or vesicles. The protein domains and GO terms that correspond to each set of proteins that are unique to a specific sample set are shown in Figures 25-29.

Figure 24. Venn diagram of similarity across sample proteins  
Numbers in parentheses represent the percent similarity between the proteins across sample types.

Proteins unique to vesicles included: calcium-binding protein (fluke), tubulin, myosin heavy chain, myosin light chain, paramyosin, tropomyosin, calreticulin, calcium ATPase, translationally-controlled tumor protein (TCTP)/histamine-releasing factor, and arginase. Calcium-binding protein, tubulin, myosin heavy chain, myosin light chain, paramyosin, and tropomyosin are all related to motor activity and microtubule-based movement and are likely used in early stages of human host invasion to guide the vesicles to their target. The role of TCTP/histamine-releasing factor is unknown, but it has been shown to bind to tubulin and has a high affinity for calcium. It is also the binding target for the anti-malarial compound artemisinin. The reason that so many of these proteins are uniquely found in the mechanically-induced sample compared to the lipid-induced sample may be related to the method used to collect the lipid-induced secretions. Cercarial bodies and heads were separated from lipid-induced secretions by centrifugation (Knudsen, Medzihradszky et al. 2005). This process may have also separated out the aggregated vesicular membranes, where proteins related to vesicular movement were attached. Mechanical induction secretions were separated by scraping vesicles from the surface of the plate, which retained

the vesicular membrane in the sample. Calreticulin is implicated in protein folding and may be degraded in the lipid-induced secretions. Both calcium ATPase and arginase are metabolic enzymes that are responsible for extrusion of calcium and nitrogen respectively and, as such, would not be expected to be contained in the vesicles. Calcium ATPase contains a transmembrane domain.

Secretion proteins that did not show homology to either of the other two sample sets include: Cu,Zn-superoxide dismutase, ferritin-2 heavy chain, 6-phosphofructokinase, fatty acid-binding protein, calpain, cysteine protease inhibitor, and dynein light chain. Cu,Zn-superoxide dismutase, ferritin-2 heavy chain, 6-phosphofructokinase and fatty acid-binding protein are all soluble proteins. Calpain is an intracellular cysteine protease that is regulated by calcium. Its inhibitor is also unique to the secretions sample. As raised by Knudsen *et al.*, one possible reason for the presence of soluble proteins in the vesicle secretions is that the secretions do not just contain vesicle proteins, but also proteins contained in the cytosol of the acetabular glands (Knudsen, Medzihradszky et al. 2005). With the exception of dynein light chain, this could explain the presence of all of the proteins unique to the lipid-induced sample.

The proteins found in the tegument were quite different than those found in the vesicles and secretions, including such proteins as amidase, dysferlin, aquaporin, and many unidentified proteins. These proteins, not surprisingly, are all related to transport.

To determine the evolutionary relationships between the proteins contained in each sample set, a phylogenetic tree was created for each, as shown in Figures 30-32. The trees were generated using the alignment files resulting from the CLUSTALW alignment of each sample set. Proteins were then assigned to phylogenetic groups as labeled on the trees according to the natural groups they would fall into if the tree was cut just below the main branch. Table 8 provides full details about the protein domains and GO functions related to the proteins contained in each phylogenetic group for each sample set.

The vesicle, secretion, and tegument proteins seem to have four, six, and three major phylogenetic groupings respectively. In the vesicles there are four major phylogenetic groups. Group 1 is very large and represents 55 proteins with a diverse set of functions including calcium-binding protein and microtubule and motor-based movement proteins. Group two has 17 members representing mainly chaperones and the elastases. Groups three and four are very small with glycolysis and metabolism represented. In the secretions there are three major groups. The chaperones, calcium-binding proteins, and elastases group together in the same major phylogenetic group, group one. Group two contains glycolytic and metabolic enzymes as well as two antigenic proteins. Group three relates to proton, electron, and iron transport as well as microtubule-based processes. In the tegument there are also 3 major groups. Group one is the largest group representing a diverse set of processes including transport, protein modification, biosynthesis and targeting, and metabolism. Group two contains only proteins related to transport and group three contains proteins related to exocytosis/vesicle docking and nucleotide metabolism.

### *Protein Domain/Gene Ontology Annotation and Statistical Analysis*

All proteins in each of the sample sets were annotated with GO terms and protein domains using InterProScan. Domains and GO terms with an e-value less than  $1 \times 10^{-5}$  were considered significant. A partial example of the raw results generated by InterProScan is provided in Figure 33. A Perl script (Appendix J) was written to parse the raw results into 1) counts of GO terms (Appendix F), 2) counts of protein domains (Appendix G), 3) matrices of sequence identifier vs. GO terms, and 4) matrices of sequence identifier vs. protein domains. The matrices were used as input files for a Matlab script (Appendix J) that computed the entropy of each GO term (Appendix H) and protein domain (Appendix I).

Entropy was calculated for each attribute (protein domain or GO id) and used to determine the most statistically significant GO terms and protein domains. The overall information (I) contained in a data set is equal to the amount of information needed to decide if an arbitrary sample in S belongs to P or N, for example. Entropy ( $E(A)$ ) represents the expected information needed to classify objects in all subtrees, while information gain ( $G(A)$ ) represents the encoding information that would be gained by branching on A. The formulas used in these calculations are as follows:

$$I(p, n) = -\frac{p}{p+n} \log_2 \frac{p}{p+n} - \frac{n}{p+n} \log_2 \frac{n}{p+n}$$

$$E(A) = \sum_{i=1}^v \frac{p_i + n_i}{p+n} I(p_i, n_i)$$

$$Gain(A) = I(p, n) - E(A)$$

Low entropy values correspond to high information gain values. In the entropy calculation tables in Appendix H, the columns “yy”, “ny”, “nn”, and “yn” indicate how many times a GO term or protein domain occurred in both samples, one but not the other, and neither sample. The table headings correspond to these entries; the sample type that is listed first

Figure 33. InterProScan raw data file example

corresponds to the first value in each of those four columns (y, n, n, y). For example, if the table heading indicates the calculations are for “vesicles vs. secretions”, then the “ny” column corresponds to a GO term not occurring in the vesicles but occurring in the secretions.

### *Gene Ontology Analysis*

Detailed GO annotation data are provided in Appendix F and visual representations of categories Biological Process, Molecular Function (I and II), and Cellular Component are provided in Figures 34-37 respectively.

The most represented GO terms in the vesicle proteins in the category Biological Process include protein folding (12.35%), glycolysis (9.88%), cellular protein metabolism (7.41%) and proteolysis (4.94%). The most represented term in the Cellular Component category is cytoplasm (6.17%). The most represented Molecular Function is by far ATP binding at 19.75%, followed by unfolded protein binding (11.11%), calcium ion binding (8.64%) and protein binding (8.64%).

The secretions proteins have glycolysis as the most represented term under Biological Process (18.87%) followed by proteolysis (9.43%) and protein folding (7.55%). Under the Cellular Component category intracellular, cytoplasm, nucleosome, and nucleus are all evenly represented at 5.66%. Under the Molecular Function category calcium ion binding is most represented (9.43%) followed by oxidoreductase activity and ATP binding (both 7.55%). Secretions have a slightly higher representation of catalytic and enzymatic activity than vesicles (5.6% vs. 3.7%).

Not surprisingly, the tegument proteins have transport as the most represented Biological Process (6.98%) followed by protein modification (4.65%). Under Cellular Component integral to membrane (9.3%) and membrane (6.98%) are most represented. Under Molecular Function calcium ion binding, transporter activity, and hydrolase activity are equally represented (4.65%).

Figure 34. % of sequences corresponding to GO annotations from category biological process

Figure 35. % of sequences corresponding to GO annotations from category cellular component

Figure 36. % of sequences corresponding to GO annotations from category molecular function (I)

Figure 37. % of sequences corresponding to GO annotations from category molecular function (II)

The control samples have regulation of transcription (7.10%), protein amino acid phosphorylation (5.81%), metabolism (5.16%), cation transport (4.52%), and transport (4.52%) as the most represented terms under the Biological Process category. Under the category Molecular Function, the most represented terms include: ATP binding at 11.61%, DNA binding at 7.74%, catalytic activity and protein kinase activity both at 5.81%, and calcium ion binding at 5.16%. Membrane (11.61%), integral to membrane (10.32%), and nucleus (7.74%) were the most represented terms under the Cellular Component category.

Appendix H shows the entropy calculations that were performed to determine the most significant GO terms. These calculations determine the extent to which each GO term contributes to the predicted class label. The class label in this case is vesicles, secretions, tegument, or control. In comparing vesicles vs. secretions and vesicles vs. tegument ATP binding was found to be the most significant feature/GO term in determining that the protein belonged to the vesicles. Also, between vesicles and tegument, in the Cellular Component category integral to membrane was the most significant feature that determined membership in the class of tegument proteins. Between secretions and tegument, glycolysis was significant in membership in the class of secretion proteins and the cellular component membrane was significant in determining membership in the class of tegument proteins. In comparing the control samples to the vesicles and secretions samples, glycolysis was the most significant term determining membership in either vesicles or secretions, and the cellular component membrane was most significant in determining membership in the class of control proteins. In comparing control proteins to tegument proteins, transporter activity and protein modification were significant in determining membership in the class of tegument proteins and DNA binding and nucleus were significant in determining membership in the class of control proteins.

These results are summarized in Table 9 below. The values in the table indicate GO terms which are significant in determining whether a sample belongs to one sample set versus another. The values 'V', 'S', and 'T' in parentheses indicate which sample class the term favors.

Table 9. GO terms with highest entropy

	V	S	T	C
V		Molecular Function: ATP binding (V)	Molecular Function: ATP binding (V); Cellular Location: integral to membrane (T)	Biological Process: glycolysis (V)

### ***Protein Domain Analysis***

Detailed protein domain annotation data are provided in Appendix G and a visual representation of the data is provided in Figure 38.

In the vesicle samples, three different chaperonin domains are all highly represented (4.94-7.41%) as well as an ATPase domain, two EF-hand domains, and a thioredoxin fold domain, while peptidase domains are represented at about 3.7%. In the secretions, the EF-hand domain is represented in 9.43% of proteins and the thioredoxin fold is represented in 7.55% of proteins, followed by peptidases, dehydrogenase, and histone fold and core all represented in 5.66% of proteins. This corresponds to the GO term percentages that showed that secretions had higher representation of enzymatic and catalytic activity. The

Figure 38. % of sequences corresponding to InterPro protein domains  
Only showing those protein domains represented in > 3% of sequences

tegument samples showed calcium/lipid-binding, thioredoxin-like fold, antigen, tetraspanin, and calponin-like actin-binding being equally represented. The control samples indicated protein kinase and protein kinase-like domains being represented very highly (18.60-20.93%), as well as thioredoxin fold, EF-hand type, and hydrolase.

Chaperonin domains are significant in classifying a protein as belonging to vesicles over controls, secretions, and tegument: each of four different chaperonin domains contributes to classifying a protein as being in the vesicles over the controls, chaperonin TCP-1 is also significant in classifying a protein as belonging to vesicles over secretions, and chaperonin Cpn60/TCP-1 in classifying a protein as belonging to vesicles over tegument. The domains histone core, lactate/malate dehydrogenase, and L-lactate/malate dehydrogenase all contribute equally to classifying a protein as belonging to secretions over controls. Calcium/lipid-binding region is somewhat significant in classifying a protein as belonging to the tegument set over the control set. Calcium/lipid-binding region, CD9/CD37/CD63 antigen, and tetraspanin all contribute to classifying a protein as tegument over vesicles. Similarly, calcium/lipid-binding region, CD9/CD37/CD63 antigen, tetraspanin, *and* thioredoxin-like fold contribute to classifying a protein as belonging to tegument over secretions.

These results are summarized in Table 10 below. The values in the table indicate protein domains which are significant in determining whether a sample belongs to one sample set vs. another. The values 'V', 'S', and 'T' in parentheses indicate which class/sample set the domain favors.

Table 10. Protein domains with highest entropy values

## **D. Summary**

A total of 177 proteins found in *S. mansoni* cercarial secretions and adult outer tegumental membrane were analyzed for the presence of conserved motifs using MEME and MAST. A 5-amino acid motif was enriched in the vesicles and found across a total of 11 sample proteins and 2 proteins from an orthologous species, *S. japonicum*. A secretion model was proposed based on functional analysis of the motif and the 13 proteins found to contain it. Sample sets were analyzed for homology using BLAST and CLUSTALW and were annotated with protein domains and GO terms using InterProScan. Methods were developed using Perl, BioPerl, and Matlab for processing InterProScan raw data and determining the most represented, as well as the most statistically significant motifs and GO terms. This data was used to theorize about the effects of the lipid induction versus tail shearing induction experimental methods as well as to analyze the proteins containing the proposed conserved motif.

## **V. CONCLUSION**

### **A. Overview of Significant Findings**

A five amino acid motif, x[K/R]xGE, was found across 12 sample proteins including calreticulin, myosin light chain, calcium binding protein, endoplasmin, protein disulfide isomerase, thioredoxin, thioredoxin peroxidase 1a, thioredoxin 2, and elastases 1a, 1b, and 2a. The mechanically-induced sample was enriched for the motif. It was also found in immunophilin and AUT1 in the orthologous species, *S. japonicum*. These proteins represent three major functions: calcium binding, chaperone (protein folding) activity, and protease activity. The first position of the motif is nonconserved, in the second position is the basic residue lysine or arginine (arginine being specific to the elastases), the third position is nonconserved, in the fourth position is the nonpolar residue glycine, and in the fifth position is the acidic residue glutamic acid. The motif was found at the N-terminal between amino acid 27 and 110, except in the thioredoxin peroxidases, where it was found

close to the C-terminal. It was found downstream from a signal peptide in 7 of the 12 sample proteins.

A surprising finding was that the overall percentage of proteins within each sample set that were predicted to contain a signal peptide was significantly lower than the percentage of the control set found to contain a signal peptide. 11% of the vesicles, 9% of the secretions, and 7% of the tegument proteins were predicted to contain a signal peptide in comparison to 23% of control proteins.

The automated workflow developed during this thesis study provides a reliable method for determining which protein domains are most significant. The functional annotation generated in this thesis study correlates well with conclusions reached in the proteomic study of cercarial secretions conducted by Knudsen *et al.*, including: 1) proteins related to calcium-binding and regulation were enriched in the mechanically-induced, as well as in the lipid-induced secretion samples, and 2) EF-hand motifs were present in many of the vesicle proteins (Knudsen, Medzihradszky *et al.* 2005). The Molecular Function Comparison I chart in Figure 36 shows that calcium-binding is one of the most represented GO terms in both the vesicles and secretion samples, and the Protein Domain Comparison chart in Figure 38 shows that the EF-hand motif is one of the most represented in the vesicle and secretion samples. This thesis analysis also revealed some unexpected differences between the secretion and vesicle proteins: 1) the biological process protein folding is almost 5% higher in the vesicles than secretions, 2) the molecular function ATP binding is about 12.5% higher in the vesicles than in the secretions, and 3) the biological process glycolysis is almost 10% higher in the secretions than in the vesicles. Entropy analysis revealed that the molecular function ATP binding and several chaperone domains were significant in classifying proteins as belonging to the vesicles over the secretions and the controls. Analysis of the proteins found to be unique to either the vesicle or secretion samples resulted in motor activity and microtubule-based movement being unique to the vesicles and some soluble proteins being unique to the secretions. Possible explanations for this are discussed in the next section.

## **B. Consideration of Findings in Context of Current Knowledge**

The motif was found to not be any of the following: a phosphorylation site, glycosylation site, protease recognition motif, elastase recognition motif, or ER-type signal peptide. It is proposed to be a pro-domain that signals proteins to be shuttled off into special secretory vesicles from the Golgi apparatus. It may be a PC recognition site, as PCs are known to cleave on the C-terminal side of sites composed of single or paired basic amino acids e.g. lysine or arginine (K/R). It bears similarity to the motif found in the malarian parasite, which was experimentally proven to be essential for the export of 320 soluble and insoluble proteins. Similarly to the *Schistosoma* proteins containing the x[K/R]xGE motif, not all of the *Plasmodium* (pfEMP1) proteins found to contain a conserved motif had a predicted signal peptide.

A possible explanation for the low percentage of signal peptides in the adult tegument sample is that the quality of the tegument sequences is lower than the vesicle and secretion samples, resulting in very short sequences in many cases where the signal peptide, if it existed, is missing. Signal peptides may be less frequent in the vesicle and secretion samples because they come from *Schistosoma* cercaria and, as discussed on page 25, cercaria may have evolved sophisticated invasion mechanisms that do not always employ the traditional eukaryotic signal peptides with which SignalP has been trained. The control sample contains proteins from all stages of *S. mansoni* and has a higher percentage of signal peptides. This may be because the life cycle stages other than cercaria use more traditional signal peptides. Also, GO analysis of the control sample shows that 11.61% and 10.32% of proteins belong to the Cellular Location categories membrane and integral to membrane respectively. This is in contrast to the vesicle and secretion samples, neither of which have membrane or integral to membrane as one of the most represented cellular locations; only 3.7% of vesicle proteins have a cellular location of membrane and only 1.89% of secretion proteins had a cellular location of integral to membrane. Perhaps *S. mansoni* employs more traditional signal peptides for membrane proteins and less traditional signal peptides for proteins that are secreted extracellularly. As Bendtsen *et al.*

points out, it is important to note that a negative SignalP prediction does not necessarily mean that the protein is not secreted as some are exported via “non-classical and leaderless pathways” (Bendtsen, Nielsen et al. 2004).

The protein domains and GO terms found to be significant or unique to the vesicle or secretion proteins are likely to be the result of the different experimental sample collection methods. The lipid-induced sample was collected by centrifuging to separate out cercarial bodies and tails from the secretions, while the mechanically-induced sample was collected by scraping vesicles from the surface of the plate. The first method may have caused some of the vesicular membranes, in which some of the chaperone-related proteins may be inserted, to be separated out from the sample along with the cercarial tails and bodies. It may have also resulted in the collection of non-vesicle-specific proteins, such as the cytosolic contents of the acetabular glands. The latter method likely retained most of the vesicular membrane and not as many non-vesicle-specific proteins, resulting in a cleaner sample.

### **C. Theoretical Implications of the Findings**

If the proposed motif can be experimentally validated as necessary for certain proteins to be exported, it could be used to predict secreted proteins. As the motif is present on proteins that are directly exposed to the host and likely to contribute to virulence, it could potentially be used as a target against which a preventative topical drug treatment could be designed. Antigenic variation within proteins makes it difficult to target specific proteins, but if a common motif exists across multiple proteins, a drug could be designed to target/interact with that motif and have activity against multiple virulence factors (the proteins that contain the motif) at once. The drug could be specifically designed to interfere with one or more of the three main functions identified within the proteins found to contain the motif: calcium ion binding, protein folding, or serine protease activity.

The differences between the proteins isolated in the vesicle and secretion samples provide insight into the effects of the different experimental sample preparation methods. The mechanical induction method produced a sample that contained proteins that were more specific to cercarial secretions than the lipid-induced method.

## **VI. DISCUSSION**

### **A. Limitations of the Study**

This study was limited in that it was not complimented by laboratory investigation which could verify that the motif is indeed essential for protein export via secretion vesicles. Also, this study was based on qualitative rather than quantitative proteomic data, which could provide information about which proteins are up and down regulated in secretions. The relatively small sample sizes made it difficult to achieve good MEME e-values. This in turn meant only smaller MAST databases could be searched using the motif revealed by MEME, resulting in larger MAST e-values. A larger sample size would improve e-values of both the MEME and MAST searches. A larger sample size would also allow clustering of the samples based on all sequence features (GO terms and protein domains). Other limitations include the fact that SignalP was not trained on any *S. mansoni* sequences and the fact that GO annotations are not available for every protein domain.

### **B. Recommendations for Further Research**

The proposed conserved motif elucidated in this thesis study needs to be experimentally validated. The ability to transfect *Schistosoma* has been established (Yuan, Shen et al. 2005), as well as the ability to express *Schistosoma* proteins in a heterologous system (Price, Doenhoff et al. 1997). A mutation could be introduced into the proposed motif in the 11 proteins found to contain it and then a reporter gene could be used to track whether the proteins are secreted or not. If the mutation is shown to prevent secretion, then a recombinant expression system could be used to produce large amounts of the proteins as potential antigens for immunological studies.

Additional MEME and MAST iterations should be performed to increase the understanding of the proposed motif or elucidate other conserved motifs. New MAST databases for motif searching could be developed using the larger number of public sequences that are becoming available. All publicly available *Schistosoma* sequences that are annotated with cellular location and life cycle stage could be downloaded, subdivided according to life cycle stage and/or cellular location, and analyzed to search for corresponding conserved motifs and significant domains. The sensitivity of the neural network behind SignalP could be specifically trained on *Schistosoma* proteins to improve its sensitivity and specificity.

The methods presented here for automated analysis of InterProScan raw data could be enhanced in a variety of ways. The Perl and Matlab scripts could be built into an automated workflow and presented as a web application that allows the end-user to submit raw data from InterProScan to retrieve corresponding domain matrices, GO matrices, and entropy calculations. An option could be built into the application that would allow the end-user to automatically extract a smaller matrix from a larger one, based on sequence identifiers, for purposes of being able to focus on specific sets of sequences and their corresponding domains and GO terms within a data set. This was done manually in this thesis study for proteins that were either unique to a sample set and that contained the proposed motif. Analysis of entropy data could be automated such that the most significant domains and GO terms are automatically presented to the user, perhaps in the table format shown in Tables 9 and 10.

## APPENDICES

### Appendix A: Summary of Sample Data Sets

Following are tables listing all samples used in this study including cercarial vesicles (induction by tail shearing), secretions (induction by skin lipid) and adult tegument. The three sample sets were obtained as detailed in the Methods- Samples and Subjects section. Column heading of sample sets: “Phylo” = phylogenetic group corresponding to phylograms in Results section on pages 50-52. “S?” indicates whether or not a signal peptide was predicted by SignalP. The last column, “KxGEx Motif?”, indicates whether or not the sequence contains the motif found in MEME #3.

## Appendix K: Permission To Use Figures

**Permission to use figures 2, 3, 4 (Dorsey, Cousin et al. 2002):**

From: "Jones, Jennifer (ELS-OXF)" <J.Jones@elsevier.co.uk>  
To: "schmidbauer2@comcast.net" <schmidbauer2@comcast.net>  
Subject: RE: Obtain Permission  
Date: Monday, June 05, 2006 3:50:26 AM

Dear Amy Schmidbauer

We hereby grant you permission to reproduce the material detailed below at no charge in your thesis subject to the following conditions:

1. If any part of the material to be used (for example, figures) has appeared in our publication with credit or acknowledgement to another source, permission must also be sought from that source. If such permission is not obtained then that material may not be included in your publication/copies.

2. Suitable acknowledgment to the source must be made, either as a footnote or in a reference list at the end of your publication, as follows:

"Reprinted from Publication title, Vol number, Author(s), Title of article, Pages No., Copyright (Year), with permission from Elsevier".

3. Reproduction of this material is confined to the purpose for which permission is hereby given.

4. This permission is granted for non-exclusive world English rights only. For other languages please reapply separately for each one required. Permission excludes use in an electronic form. Should you have a specific electronic project in mind please reapply for permission.

5. This includes permission for UMI to supply single copies, on demand, of the complete thesis. Should your thesis be published commercially, please reapply for permission.

Yours sincerely

Jennifer Jones

Rights Assistant

Dear Dr. Cousin,

Dr. Fred Lewis advised me to seek your permission, in addition to his and the publisher's, to use figures 1, 10, and 23a from the publication "Ultrastructure of the *S. mansoni* cercaria" (Micron Vol. 33, pages 279-323). I am doing a thesis project at Indiana University that is a proteomic study of the *S. mansoni* secretome. Would you be willing to grant this permission?  
thank you,

Amy Schmidbauer

Amy,

You have my permission to use those figures, but I may not have the final say on the subject. You will also need to contact the publisher, Pergamon Press, which produces the journal *Micron* in which the article appears. Although unlikely, there may be some copyright issues involved. Also, please contact Carolyn Cousin at ccousin@udc.edu for her consent as well. Dr. Stirewalt is no longer alive, and Charles Dorsey is in very ill health.

Subject: permission to use figure

Dear Dr. Lewis,

I am doing a thesis project at Indiana University that is a proteomic study of the *S. mansoni* secretome. I am writing to seek permission to use figures 1, 10, and 23a from the publication "Ultrastructure of the *S. mansoni* cercaria" (*Micron* Vol. 33, pages 279-323) in my thesis. This paper was extremely helpful to me in gaining an understanding of the morphology of this parasite. Would you be willing to grant this permission?

thank you,

Amy Schmidbauer

**Permission to use figure 5** (Jones, Gobert et al. 2004):

From: "Malcolm Jones" Malcolm.Jones@qimr.edu.au

Subject: Re: permission to use figure  
Date: Sunday, May 14, 2006 5:42:45 PM

Dear Ms Schmidbauer,  
Very happy to grant the permission. Thanks indeed for asking. Would you prefer the original digital image, or will you make a copy from the published article?

Best wishes

Malcolm

Dear Dr. Malcolm Jones,

I am doing a thesis project at Indiana University that is a proteomic study of the *S. mansoni* secretome. I am writing to seek permission to use a figure from one of your publication in my thesis- Figure 2 from "The cytoskeleton and motor proteins of human schistosomes and their role in surface maintenance and host-parasite interactions" from Bioessays Vol. 26 No. 7 pages 752-765 2004.

thank you,

Amy Schmidbauer

## **CURRICULUM VITAE**

### **CONTACT INFORMATION**

Amy L. Schmidbauer  
4720 Stoughton Court  
Indianapolis, IN 46254  
317-293-7821  
317-250-3071 (cell)  
aschmidb@iupui.edu  
alschmidbauer@dow.com

---

### **EDUCATION**

2002-2006	Indiana University Purdue University Indianapolis M.S. Bioinformatics (expected)
1998	International Society of Seed Technologists R.S.T. (Registered Seed Technologist)
1989-1993	University of Illinois at Urbana-Champaign B.S. Microbiology (Major: Microbiology, Minor: Chemistry)

---

### **PROFESSIONAL AFFILIATIONS**

International Society for Computational Biology (ISCB), 2005-present  
Symposium on Applied Computing Machinery, Bioinformatics Track Reviewer 2005-7  
Crop Science Society of America

---

### **PUBLICATIONS**

Indiana Bioinformatics Conference, 2006, Poster: "Information Theoretic Approaches to Analyzing Protein Domain and Gene Ontology Annotation Data: A Study of *Schistosoma mansoni*"

---

## **PROFESSIONAL EXPERIENCE**

**June 2006- Present**

### **Bioinformatics Specialist**

Dow AgroSciences, Indianapolis, IN  
Discovery Research Information Management

1. Lead the development of bioinformatics strategy.
2. Manage bioinformatics strategy implementation projects.
3. Lead external collaborations and intern projects.
4. Develop expertise in Pipeline Pilot and develop automated bioinformatics workflows.

**Oct 2001- June 2006**

### **Business & Systems Analyst**

Dow AgroSciences, Indianapolis, IN  
Discovery Research Information Management

1. Act as liaison between research community and Dow IS.
2. Act as partner project manager for biotech-related IS projects including process mapping, business requirements analysis, solution analysis, application testing and implementation, and user training and support.
3. Participate on Six-Sigma and Design for Six-Sigma projects for process improvement or new process development related to recombinant and native culture collections.
4. Provide informatics support for Microbiology and Natural Products groups, including query/report development and data mining support.
5. Provide commercial software evaluations, comparisons, and recommendations based on researchers' needs.
6. Subject Matter Expert for Spotfire. Lead monthly Spotfire user group, provide user training and support, perform software upgrades, configure guides and tools.
7. Subject Matter Expert for Nautilus LIMS. Lead a subject matter expert group, provide workflow configuration, user support and training, application troubleshooting.
8. Develop and maintain Discovery and Bioinformatics websites.

**Apr 2001-Oct 2001**

**LIMS Analyst**

Dow AgroSciences, Indianapolis, IN  
Bioinformatics Group, Genomics

1. Develop expertise in Nautilus LIMS to enable high-throughput screening processes.
2. Map laboratory processes and develop corresponding workflows in Nautilus LIMS to track laboratory processes and data.
3. Provide Nautilus troubleshooting, user support and training.
4. Perform software upgrades as necessary.

**Mar 1998- Mar 2001**

**Assistant Lab Manager**

Cargill Hybrid Seeds  
Aurora, IL  
Quality Assurance

1. Supervise daily lab activities.
2. Provide process and lab improvements to increase efficiency and effectiveness and meet tight deadlines.
3. Provide employee development opportunities and performance evaluations.
4. Make decisions to certify or fail commercial seed lots for shipment.
5. Manage large-scale project to test and certify all non-GMO seed lots as non-GMO.
6. Mentor associate at Syngenta Seeds in studying for RST exam.

**Mar 1996- Mar 1998**

**Seed Technologist**

Cargill Hybrid Seeds  
Aurora, IL  
Quality Assurance

1. Develop expertise in International Seed Testing Association (ISTA) rules and procedures.
2. Ensure seed quality is assessed according to ISTA rules and seed quality matches official lot tags.
3. Develop new high-throughput analytical methods for testing genetic insect and herbicide resistance traits.
4. Perform high-throughput germination, purity, and trait testing.
