Background: Hydroxychloroquine (HCQ) is currently being examined for COVID-19. No previous meta-analysis has evaluated its side effects versus placebo. We conducted this meta-analysis to compare the safety of HCQ versus placebo.

Methods: Two authors independently searched PubMed and EMBASE databases for randomized controlled trials (RCTs) of adults comparing the adverse events (AEs) of HCQ versus placebo for any indication. Peto odds ratios (Peto ORs) and 95% confidence intervals (CIs) were calculated based on random-effects models. The heterogeneity ($I^2$) was assessed using Cochran’s Q test.

Results: Nine RCTs (eight were double-blind) with a total of 916 patients were included. HCQ caused significantly more skin pigmentation than placebo (Peto OR, 4.64; 95% CI, 1.13 to 19.00; P-value=0.033; $I^2=0\%$). The increase in other AEs did not reach statistical significance: rash (Peto OR, 1.11; 95% CI, 0.3 to 3.77; P-value=0.03; $I^2=0\%$); gastrointestinal AEs (Peto OR, 1.43; 95% CI, 0.55 to 3.72; P-value=0.46; $I^2=15.17\%$); headache (Peto OR, 1.94; 95% CI, 0.65 to 5.78; P-value=0.23; $I^2=9.99\%$); dizziness (Peto OR, 1.32; 95% CI, 0.49 to 3.52; P-value=0.58; $I^2=0\%$); fatigue (Peto OR, 2.13; 95% CI, 0.76 to 5.98; P-value=0.15; $I^2=0\%$); and visual AEs (Peto OR, 1.61; 95% CI, 0.76 to 3.41; P-value=0.22; $I^2=0\%$). Cardiac toxicity was not reported.

Conclusions: This meta-analysis of RCTs found a significantly higher risk of skin pigmentation in HCQ users versus placebo. More data are needed to evaluate HCQ in the context of COVID-19 treatment.
INTRODUCTION

The 4-aminoquinoline compounds such as chloroquine (CQ) and its hydroxylated analog, hydroxychloroquine (HCQ), have been widely used in the treatment of malaria [1]. Additionally, HCQ is an approved treatment for a number of autoimmune diseases such as systemic lupus erythematosus (SLE) and rheumatoid arthritis (RA) [2]. Further observations highlight its potential efficacy in a wide range of conditions, including endocrine diseases, coagulopathies, and infectious diseases [3]. Due to its lower toxicity, HCQ is preferred over CQ in rheumatic conditions. The definite mechanism of action of HCQ in controlling these diseases is unknown. HCQ is thought to work by interfering with lysosomal activity, inhibition presentation of antigens and Toll-like receptor signaling, and termination of circulating immune complexes [4]. HCQ has a very long half-life due to extensive tissue uptake. It is available only in oral dosage forms and needs to be taken with food to reduce the risk of gastrointestinal adverse reactions [2].

Since there is no specific approved therapy for Coronavirus Disease 2019 (COVID-19) yet, multiple agents with antiviral activity are being used as possible therapies such as HCQ, CQ, remdesivir, and lopinavir-retonavir [5, 6, 7, 8]. In addition to its immunomodulatory effects, HCQ has some antiviral activity [6]. Despite being a relatively safe and low-cost drug, HCQ can cause a number of side effects and its toxicity is not well understood, partially due to the limited number of patients (low statistical power) in the published randomized controlled trials (RCTs). Therefore, it is useful to conduct this first meta-analysis pooling of all data on its adverse reactions to better understand its safety compared to placebo. The objective of this study is to compare the side effects of HCQ to placebo through a meta-analysis of RCTs of adults who received hydroxychloroquine.
METHODS

This meta-analysis followed the Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) guidelines.

Search strategy and selection criteria

Articles were identified via PubMed, EMBASE, and Cochrane Library bibliographic databases (see Appendix A for search strategy). No restrictions were placed on language or publication date. The searches and data extractions were completed independently by two authors until March 19, 2020. Any disagreement in the literature screening or data extraction was resolved through discussion. We included comparative RCTs evaluating safety in adults who received HCQ therapy versus placebo. RCTs that did not report specific adverse events (AEs) were excluded.

Outcomes, data analysis, and risk of bias

The outcomes of interest were the frequency of AEs. Peto odd ratios (Peto ORs) with 95% confidence intervals (CIs) were assessed using random-effects models, and heterogeneity ($I^2$) was evaluated using Cochran’s Q test. We examined the study quality using the Cochrane risk of bias tool for RCTs (low, unclear, or high) [9]. We performed all analyses using the Comprehensive Meta-Analysis Version 3 software (Biostat, Englewood, NJ, USA).

RESULTS

Search results and study characteristics

The search process identified 713 articles, and a total of nine RCTs [10-18] were included after screening by title/abstract followed by full text review (Figure 1). This meta-analysis included a total of 916 patients. The characteristics of studies are summarized in Table
1, and the study quality assessment is summarized in Table 2. Eight RCTs were double-blind [11-18], and one was single-blind [10]. Only three RCTs were funded by drug companies [11, 12, 18]. Studies were conducted on four different continents and included patients with a variety of indications. The average age of patients was over 60 years in only one study [17]. The duration of therapy was ≥12 weeks and the HCQ daily dose ranged between 200 and 400 mg/day, except in one study, in which 800 mg/day was also used [13].

**Study outcomes**

Skin pigmentation occurred significantly more with HCQ than with placebo (Peto OR, 4.64; 95% CI, 1.13 to 19.00; P-value=0.033; $I^2=0\%$) [Figure 1]. Although there was a numerical increase in the rate of AEs, no statistically significant differences were observed in the rate of rash (Peto OR, 1.11; 95% CI, 0.3 to 3.77; P-value=0.03; $I^2=0\%$), gastrointestinal AEs (Peto OR, 1.43; 95% CI, 0.55 to 3.72; P-value=0.46; $I^2=15.17\%$), headache (Peto OR, 1.94; 95% CI, 0.65 to 5.78; P-value=0.23; $I^2=9.99\%$), dizziness (Peto OR, 1.32; 95% CI, 0.49 to 3.52; P-value=0.58; $I^2=0\%$), fatigue (Peto OR, 2.13; 95% CI, 0.76 to 5.98; P-value=0.15; $I^2=0\%$), or visual AEs (Peto OR, 1.61; 95% CI, 0.76 to 3.41; P-value=0.22; $I^2=0\%$) [Figures S1-6 in Appendix A]. No cardiac toxicity was reported in the studies.

**DISCUSSION**

In this study, we evaluated the AEs of long-term use of HCQ, as the use of HCQ had been increasing recently with the current COVID-19 pandemics. In this meta-analysis, we attempted to examine systemic AEs of HCQ based on data from RCTs. To the best of our knowledge, this meta-analysis is the first attempt to examine such AEs in RCTs. One strength in
this meta-analysis results is the low statistical heterogeneity as measured by $I^2$, which indicates low variability in the effects of intervention being assessed in the different studies. However, it is important to consider that meta-analyses of AEs have some general pitfalls [19]. Therefore, the findings of this meta-analysis should be interpreted with caution.

Of all screened studies, we included 9 RCTs. The included studies were mainly in relation to autoimmune diseases and were superiority studies. In addition, the daily dose of HCQ daily was 200 – 400 mg/day. The current use of HCQ in COVID-19 is mainly short term, and thus the observed AEs in this study might not occur in patients with COVID-19. We observed no significant increase in the occurrence of visual AEs. However, retinopathy was considered an important AE in long-term users [20].

An important observation in this meta-analysis is the occurrence of skin pigmentation significantly more with HCQ than with placebo. We cannot rule out the possibility of insufficient statistical power to detect statistically significant differences in other AEs. However, we included as many studies as we can by not limiting the inclusion criteria to specific indication to catch all studies reporting AEs of HCQ. Skin darkening is an important AE and potentially a cosmetic problem, as complete resolution is rare. The incidence of HCQ-related skin pigmentation was reported to be 7% in patients with SLE and was not dose or duration dependent [21]. However, in one study the occurrence of skin pigmentation occurred after a median duration of 32 months and a median cumulative dose of 361 g [22]. Since this AE may not occur in some patients receiving HCQ for short duration and the included studies used it for several weeks, it might not be relevant in the context COVID-19 except when used for a prolonged period in prophylaxis, which is currently being investigated [8]. Although the mechanism of development of skin pigmentation is not well characterized, one study indicated that a possible mechanism is
the presence of both melanin and hemosiderin in the dermis [23]. In addition, a previous study identified multiple risk factors, such as bruising, the use of specific medications (corticosteroid, oral anticoagulants, antiplatelet agents), and the presence of antiphospholipid syndrome [20].

The distribution of skin pigmentation is variable and may involve lower extremities, the face, lips, and the gums [22] and may be in the form of a butterfly [24].

This meta-analysis showed no significant difference in the occurrence of skin rash with HCQ. The occurrence of skin rashes may be a characteristic of the underlying disease. In one study, the occurrence of skin rash was more common in patients who had dermatomyositis (31%) compared to those with cutaneous lupus erythematosus (3%) [25]. Skin rash was also common in patients with psoriasis and psoriatic arthritis [26]. The included studies in this meta-analysis did not include patients with these underlying diagnoses.

The occurrence of prolonged QTc interval was described in patients receiving HCQ, and discontinuation of HCQ shortened the QTc interval [27, 28]. Another potential cardiotoxicity is the occurrence of cardiomyopathy, and this was linked to older age, female gender, >10 years of therapy, high daily dose, and underlying cardiac disease and renal disease [29]. However, the occurrence of QT prolongation and cardiomyopathy were not reported in the included studies. There is concern about arrhythmias in patients with rheumatoid diseases treated with HCQ [30]. However, the included studies did not report on the occurrence of arrhythmias. Indeed, the references to cardiac toxicity included hydroxychloroquine overdoses or suicide attempts. Unfortunately, hydroxychloroquine and chloroquine in particular, are known to have been widely used in suicide attempts. Additionally, and because HCQ could prolong QTc, caution and ECG monitoring are required when using it, particularly in combination with other QTc-prolonging medications [2, 7].
Chloroquine and HCQ are metabolized by the hepatic cytochrome P450 enzyme 2D6 (CYP2D6). CYP2D6 expression is variable depending on genetic polymorphisms, and 7% of white North Americans have no functional CYP2D6 “poor metabolizer” and 1–2% have gene duplications conferring an “ultrarapid metabolizer” phenotype. The variation in CYP2D6 may also influence the variability of AEs [30]. Glucose-6-phosphate dehydrogenase deficiency, which is associated with hemolysis after using some antimalarial drugs, seems to be of less concern with HCQ [31].

In conclusion, this meta-analysis showed that skin pigmentation was the only significant AE of HCQ compared to placebo. However, the included studies mainly evaluated the use of CHQ in the treatment of autoimmune diseases and did not include the full spectrum of these abnormalities. There are certain AEs that might be secondary to the underlying condition and might not be observed in other conditions. The use of HCQ in COVID-19 is an important new development for this drug, and further analysis is needed to specifically address AEs in this population as well as to establish the efficacy.
